Tracing cloth is a finely woven fabric which is coated heavily with a starchlike compound and rolled to produce a glossy surface on one side and a dull surface on the other. The glossy surface is the one which was originally intended for use. Ink lines on it have a sharper edge, and it is easier to erase on that side without damaging the cloth. However, the dull side is now intended as the working side, because it takes ink more readily, and it can be worked on with a pencil when changes in the drawing are necessary. Cloth combines the advantages of transparency, surface quality, strength, and permanence. It can withstand repeated erasures without major loss of surface quality, and aging does not materially affect its drawing and reproduction qualities. Though paper may exceed cloth in one or more of these characteristics, it does not equal its combined advantages. The so-called linen cloth is actually cotton, sized with starch to give a surface that takes pencil and ink, and by penetrating the voids between the cellulose fiber, makes the cloth transparent for tracing and reproduction purposes.

Tracing paper, sometimes called tracing vellum, is white or slightly tinted more-or-less transparent paper which may or may not be especially prepared. The more transparent papers are used as tracing papers. Formerly, they were used almost exclusively for the ink tracing of pencil drawings made on opaque papers. Transparency was the prime requirement. Today, the usual drafting practice is to develop the master drawing directly on transparent paper from which reproductions can be made, thereby saving the time, expense, and checking involved in the tracing process. This practice means that, in addition to good transparency, the modern high-grade tracing paper must be able to withstand repeated erasures, have good pencil take, and be strong enough to withstand considerable handling. The paper should retain these qualities for a long period of time to avoid the eventual necessity of redrawing, either manually or photographically. Natural tracing papers have properties which depend on weight, method of manufacture and raw material. If made of rag, they are usually fairly strong for their weight and permanent but not too transparent. If natural papers are made with high transparency they usually possess only moderate strength and are recommended for sketching purposes where permanency is not a factor. Transparentized or prepared tracing papers answer the problem of how to combine strength plus transparency, for the added thickness that gives paper its strength usually reduces its transparency. This problem has been solved by means of a solid, stable, synthetic resin which is permanently impregnated into the thicker paper to give it high transparency.

The most recent of drafting media is film. The base material for drafting film is the DuPont polyester film called Mylar. Raw Mylar has natural dimensional stability, great tearing strength, high transparency, high age and heat resistance, and nonsolubility and waterproofness. However, raw Mylar is not a satisfactory surface for pencil drawing; it has a tendency to curl up; and static electricity builds up and holds dust on the film. Therefore, various drafting media manufacturers treat Mylar to overcome these objections and market the drafting film under trade names other than Mylar. Herculene and Stabilene are two popular drafting films.

As indicated in the foregoing paragraphs, there are many qualities to be considered in selecting a drafting medium for the job at hand. These include a consideration of whether the medium was designed to take ink or pencil or both. The color, the visual transparency, and the reproductive transparency must be considered. Also the strength, erasability, and permanence. And, most important for some engineering drawings, the dimensional stability under varying conditions of temperature and humidity.

Drafting media are available in rolls, in sheets, and in pads. Typical roll lengths are 20 yards and 50 yards and typical widths vary from 24 inches to 54 inches in 6-inch increments. Sheets are generally cut to order by the supplier, but stock of some popular sheet sizes are often kept on hand. The following sizes (in inches) are typical: 8 1/2 x 11, 11 x 17, 12 x 18, 17 x 22, 18 x 24, 22 x 34, and 24 x 36. Pads of tracing paper may also be prepared to order, but stocks are often maintained of pads of 25, 50, and 100 sheets of some sheet sizes of which the following are typical: 8 1/2 x 11, 11 x 14, 11 x 17, 14 x 17, 18 x 24.

All of the drafting media are available plain without any preprinting. But some drafting shops find it convenient and economical to order sheets with preprinted borders and, sometimes, title blocks. Sheets, rolls, and pads preprinted with nonreproducible or fade-out grid lines or guide lines are popular. The cross-section lines are printed in a special nonreproducible ink and these grids will not appear when the drawing is reproduced by diazo or photographic methods. Rolls, sheets, and pads of paper, and rolls of film, are stocked by most suppliers. Grids available include the following number of lines to each square inch: 4 x 4, 5 x 5, 8 x 8, 10 x 10, and 20 x 20.

DRAFTING ROOM SUNDRIES

Most of the basic equipment and materials used in a drafting room have been mentioned thus far in this chapter. However, there are a few common items which have not been covered.

Drafting tape, similar to masking tape, is used to attach drawings to the board. Paperweights are convenient, particularly for use on the light table or when an edge of the tracing paper must be frequently lifted to read faint lettering on a drawing being traced. Leather bags filled with lead shot are popular paperweights.

Transparent mending tape is used to repair tears in tracings and to patch holes which resulted from your leaning too heavily on the electric erasing machine. Never use cellophane tape—it shows up on the prints.

Various kinds of sharp-bladed knives and paper cutters are sometimes used in drafting rooms. The old-fashioned 14-inch or 16-inch paper shears, however, are probably best for cutting paper.

Preparations similar to talcum powder come in shaker-top containers with a felt pad on top. This powder is used to prepare the surface of cloth before it is drawn on with ink. Sprinkle the powder on the linen, rub it with the felt pad, and then shake off the excess powder.

Rubber cement is frequently used in drafting rooms to make a mosaic of work prints when the overall drawing consists of more than one sheet.

SPECIAL INSTRUMENTS

There are a number of drafting instruments which are not always required but which are very useful, and at times indispensable, for certain types of work. Some of these are used only in one highly specialized field of drafting. Others are used in several fields, and since a general knowledge of these are of value to every draftsman, their use and care are discussed in this section.

Meter Bar

The meter bar, so-called because its graduated scale is one meter in length, is the standard scale for all measurements used in constructing projections or other operations involving comparatively long distances. It is made of german silver and graduated by machine with great precision, on one side at a scale of 1:10,000 and on the reverse at a scale of 1:20,000. (See fig. 3-72.)

The bar may be used for other scales by applying a simple ratio to the distance to be scaled. For example, a 10,000-meter distance on a 1:40,000 scale will equal 5,000 meters on the 1:20,000 scale of the meter bar; or similarly, 2,500 meters on the 1:10,000 scale.

Figure 3-72.—Meter bar.

Figure 12-12.—Schematic view of helix type traveling wave tube.

tube, and eventually dissipate in the collector in the form of heat.

At the same time the electron beam is moving through the tube, the desired RF signal is fed into a slow-wave structure consisting (in this case) of a tightly wound wire called a HELIX. The phase velocity of the RF wave (or the speed at which the wave is moving forward) is made synchronous with the velocity of the electron beam.

An interaction is created between the electron beam and the RF signal. This interaction is such that the electrons in the beam are slowed by the RF field, and move down through the helix in bunches. As the electrons are slowed, they surrender energy to the RF field, resulting in great amplification of the RF signal by the time it reaches the output.

COMPONENTS

Basically, all traveling wave tubes consist of the same components, although there are many variations of each of these. These components are:

1. Electron gun, to produce the electrons and to shape them into a beam.
2. Slow wave structure, to propagate a microwave signal in such a manner as to permit interaction between the signal and the beam.
3. Collector, to absorb and eliminate the unused energy from the beam upon completion of its travel.
4. Input and output coupling devices for the transfer of energy into and out of the tube.
5. Attenuator, to isolate the input and output sections of the tube, so as to prevent undesirable oscillations.

These components and some of their variations are discussed in this section.

Electron Gun

The electron gun is the source of electrons for the beam, and is similar to the lens in a projector. Its main objective is to get as much electron current to flow in as small an area as possible, without distortion or fuzzy edges. A wide variety of gun designs have been developed in an effort to improve gun optics and to provide better beams.

Different types of cathode materials have been used as electron emitters. Two types have become generally standard: The oxide type, which has a nickel base with a barium-strontium coating; and the L-type (or dispenser) cathode which has an emitting surface consisting of porous tungsten through which barium atoms are dispensed from a chamber containing barium-strontium-oxide crystals. In addition, two other dispenser types, the pressed cathode and the impregnated cathode, are also used.

Recently a number of TWT's using control grids have been developed. This innovation permits turning the electron beam on and off rapidly with a smaller voltage swing than is required with cathode modulation of the tube without the grid.

Methods of Focusing

All TWT's require some method of holding the electron beam together as it travels through the interaction structure of the tube, because the beam tends to disperse (or spread out) as a result of the mutually repulsive forces between electrons. An electrostatic field or a magnetic field of the proper magnitude is used to confine the beam in the pencillike cylindrical shape it must maintain. The three principal types of magnetic focusing discussed here are shown in figure 12-13.

SOLENOID.—Solenoid focusing is still considered as one of the best means of obtaining a narrow, pencillike beam of electrons in an electron tube. The magnetic lines produced by the solenoid are parallel to the direction of travel of the electrons, and the solenoid can be alined accurately with the beam. This type focusing continues to be used in cases where the maximum power is required from the tube, and the physical size and weight of the tube and associated circuitry are not critical. However, in airborne equipments, the solenoid type focusing has been supplanted by other means.

The allowable error on a meter bar is 0.1 mm. for any distance. A copy of the calibration test for a bar will usually be found inside the cover of the box in which the meter bar is furnished. Older bars, for which there are no data as to accuracy, should be carefully verified before use by comparison with a standard of known accuracy.

The length of a meter bar is divided into spaces representing 100 meters each at the scale of the bar. The width of the bar is divided into 10 equal spaces by numbered parallel lines. (See fig. 3-73.) At the left end of the bar, one 100-meter space is subdivided by 10 parallel diagonal lines in such a way that distances to tenths of a meter may be scaled as illustrated in figure 3-73.

Figure 3-73.—Metric scale: a = 100.0 meters; b = 110.0 meters; c = 111.0 meters; d = 111.5 meters.

In setting a distance on the meter bar with the beam compass, place the point of the leg containing the slow-motion screw on the appropriate 100-meter vertical division line and bring the fixed point to the approximate setting at the left end of the bar. Then, holding the fixed point in your left hand, move the slow-motion screw with your right hand until the fixed point is felt to engage the groove at the correct point. The compass beam or the dividers should always be held parallel to the horizontal lines on the meter bar during a setting.

Meter bars are expensive instruments which should be carefully handled and stored. The finely ruled lines are easily marred by divider points. For this reason, take particular care to handle the beam compass or dividers lightly. Clean the bars occasionally with a soft rag and a nonabrasive metal polish. On board ship, store them where they will be least exposed to moisture and where they will be secure during periods of rough weather.

Quarter-meter scales, similar to the meter bar but only a quarter meter in length, are available at scales of 1:10,000 and 1:20,000. These should be compared with a meter bar of known accuracy before they are used.

Figure 3-74.—Foot scale: a = 1100.0 feet; b = 1110.0 feet; c = 1125.0 feet.

Foot scales are similar to meter bars in construction and use, but the lengths and values of the subdivided spaces differ. (See fig. 3-74.) The smallest direct reading is 10 feet, but 1-foot distances can be interpolated between the parallel horizontal lines as illustrated. These scales are used in plotting control points or other data where coordinates are in feet.

Pantograph

The pantograph is an instrument for copying drawings to the same, a larger, or a smaller scale. There are a number of different types of pantographs, but the principle governing them all is the same. It consists essentially of a system of bars pinned together in parallelogram form. (See fig. 3-75.) Holes are provided in the arms at certain measured intervals so that the instrument can be set to give a ratio of reduction or enlargement.

The pantograph is covered further in chapter 17.

Figure 3-75.—A pantograph.

Planimeter

Planimeters are designed to make measurements of irregular boundaries from which the number of square units of the areas inside these boundaries can be determined. (See fig. 3-76.)

After the tracing arm of the planimeter is set to the desired scale, the tracing point is placed at any convenient point on the boundary of the area to be measured. The tracing arm contains a vernier which is read and recorded. Then the tracing point is carefully guided around the entire boundary of the area to the starting point where it is reread and the reading recorded. The difference between the two readings determines the area of the traverse or other figure with an irregular boundary. This difference is used in computations to give the number of square units in the area. When the work requires special accuracy, several measurements may be taken and the average of differences used as the figure in the computations.

Some planimeters may be set so that the figure representing the area may be read directly. It is customary to make two or three readings with such instruments, using the average of the results as the figure for the number of square units in the area.

Calipers

To make a working sketch directly from a machine part, you will need special instruments to measure the part. The drafting scales are too delicate to use on machinery. If the measuring edge of the drafting scale is nicked, any measurements taken from it when you are drawing may be inaccurate.

In measuring parts of machines, a steel machinists' rule is useful. For cabinet work, use a carpenters' rule. Calipers are invaluable for making accurate measurements of machinery or tools. (See fig. 3-77.) The curved legs of the outside calipers make it possible to reach places where the rule cannot be used. Inside

Figure 3-76.A planimeter.

Figure 3-77.—Calipers for measuring machinery. a. Outside calipers. b. Inside calipers.

the calipers are adapted to measuring width of holes or gaps.

Calipers can be used for taking measurements which are accurate to within 1/64 of an inch. It takes some practice, however, to develop the right "feel" required for taking measurements this accurate. When measurements of a cylindrical piece are taken with outside calipers, the calipers should just touch the piece but be free to slide over it under their own weight. (See fig. 3-78a.) When you measure holes with inside calipers, be sure the measurement is taken in a plane exactly perpendicular to the axis of the holes. (See fig. 3-78b.)

For measurements which are accurate to less than 1/64 of an inch, a micrometer caliper is best. Figure 3-79a shows a 1-inch micrometer which will take measurements of dimensions up to 1 inch and which are accurate to within .001 of an inch. Figure 3-79b shows an enlarged view of the scales. The scale running lengthwise along the barrel has divisions representing .025 of an inch; the scale around the thimble had divisions representing .001 of an inch. To take a reading, look at the scale on the barrel first and then add to the figure there the reading on the thimble scale. It is a simple procedure, but it requires a little practice. The beginner usually has a tendency to bring the instrument into too tight contact with the object he is measuring. To prevent this, some micrometers are provided with a friction slip on the thimbles so that they cannot be tightened beyond the correct pressure.

Description and use of simple calipers, caliper squares, vernier calipers, and micro-

Figure 3-78.—Taking measurements with calipers.

meter calipers are covered in great detail in Part I Section 1 of Basic Handtools, NavPers 10085-A. The maintenance and care of the instruments are also covered in detail.

CARE OF EQUIPMENT

This chapter opened with the presentation of rules concerning the care and stowage of instruments and equipment. Throughout the chapter information relating to care, maintenance, and adjustment has been presented with coverage of both individual items and groups of items of equipment. The subject is so important, however, that it is appropriate to close the chapter on the same note.

Figure 3-79.—a. Sectional view of 1-inch micrometer. b. Enlarged view of scales.

Some people seem to have the attitude that straightedges, triangles, curves, protractors, and scales are consumables like pencil leads and erasers and that you have to expect to replace them frequently. This attitude has no merit. Properly used, handled, and stowed, these items will last for decades. Don't pound on the board with your scale when you want to emphasize a point or vent your frustration at having made an ink blot. Don't throw a triangle across the room when someone asks to borrow it. In your eagerness to knock off at the end of the day don't shove the equipment off the board and into the drawer in one great sweeping motion. Hang things up. Handle them carefully. And remember, don't use your scale as a straightedge.

Instruments can last a lifetime. Keep instruments, large and small, in their cases. Always carefully preserve the manufacturer's manual which comes with such items as the planimeter or the pantograph. It's not overdoing it to keep the cased instrument and the manual in the cardboard box in which they came from the supplier. That way your successors can find the manual. Keep track of the little containers of extra screws, points, and so on, which are sometimes furnished with instruments. These will permit you, using the manual if necessary, to make minor repairs. If wear or damage cannot be rectified by adjustment or minor repair in the drafting room, the instrument should be replaced or returned to the supplier if repair is economically feasible. Procedures for obtaining repairs and replacement items were covered in chapter 1.

CHAPTER 4

GENERAL DRAFTING PRACTICES

This chapter opens with an explanation of drafting symbols. The next topic includes the techniques of laying out and finishing drawings using the equipment and materials described in chapter 3. The conventional symbols for the lines on a drawing are discussed. The use of instruments and equipment to draw geometrical figures and curves is covered next. The dimensioning of drawings follows. The chapter presents next the types of projections and views which go to make up engineering and architectural drawings. The chapter closes with brief coverage of technical sketching.

SYMBOLS

Symbols are a part of the language of engineering drawings. Spoken languages are living things in the sense that the meaning of words may change; some words fall out of use; new words are introduced, particularly when the technology is rapidly expanding. Similarly, drafting symbols change; some are deleted; many new ones are introduced.

As a Navy draftsman you are required to use symbols which are set forth in the military standards. The standards are presented in an ever-changing series of documents which are identified by the term MIL-STD followed by a number. When you start a new project, make sure that you have the current MIL-STDs needed for the job. Check for the latest MIL-STD editions in the Department of Defense Index of Specifications and Standards, which is issued as of 31 July of each year. Also check the supplements to the Index; supplements are issued every two months between the annual editions. The Index and its supplements are issued in two parts: an alphabetical listing and a numerical listing. It is usually more convenient to use Part II—the numerical listing. Look on the table of contents of Part II for the heading "Military Standards." Your drafting symbol MIL-STDs will be, generally, at the beginning of the list of MIL-STDs. Some are as follows (these are current at the time of preparation of this book and where there have been changes issued the date shown is the date of the latest change):

Number	Title	Date
MIL-STD 1B	General drawing practice	9 Jul 63
MIL-STD-2C Change 1	Engineering drawing sizes and formats	19 Mar 64
MIL-STD-7A	Types and definitions of engineering drawings	18 Feb 64
MIL-STD-8C	Dimensioning and tolerancing	16 Oct 63
MIL-STD-9A	Screw thread conventions and methods of specifying	26 May 60
MIL-STD-10A Change 2	Surface roughness, waviness, and lay	25 Nov 63
MIL-STD-12B	Abbreviations for use on drawings	18 May 59
MIL-STD-14A	Architectural symbols	3 Sep 54
MIL-STD-15 Part No. 1	Graphic symbols for electrical and electronics diagrams part 1A	22 May 63
MIL-STD-15 Part No. 2	Electrical wiring equipment symbols for ships plans part 2	30 Oct 61

MIL-STD-15 Part No. 3	Electrical wiring symbols for architectural and electrical layout drawings part 3	30 Oct 61
MIL-STD-16C	Electrical and electronic reference designations	4 Dec 61
MIL-STD-17B Part No. 1	Mechanical symbols	23 Jan 63
MIL-STD-17B Part No. 2 Change 1	Mechanical symbols for aeronautical, aerospacecraft, and spacecraft use	23 Feb 65
MIL-STD-18A	Structural symbols	12 Aug 53
MIL-STD-20	Welding terms and definitions	14 Dec 49
MIL-STD-21	Welded-joint designs, armored-tank type	5 Oct 61
MIL-STD-22A	Welded joint design	24 Oct 56
MIL-STD-24B	Revision of drawings	28 Jun 63
MIL-STD-25 Change 1	Nomenclature and symbols for ship structure	14 Jun 56
MIL-STD-25 Change Notice 1	Nomenclature and symbols for ship structure	14 Jun 56

Many drawings continue in use for years. Therefore, you will have occasion to work with drawings which contain obsolete symbols. Also, architectural and engineering consulting firms which prepare drawings for the Navy have not always adhered closely to MIL-STD symbols. Look for a legend on the drawings; it should help you in the reading of any symbols with which you are not familiar. If there is no legend, study the drawing carefully and you should be able to deduce the meaning of unfamiliar symbols and abbreviations. MIL-STD symbols, current at the time of preparation, were used in the drawing of the illustrations for this book. However, subsequent changes in the MIL-STDs will render some of these symbols obsolete. This is exactly what you can expect to find on the drawings which you will see in practice.

LAYING OUT THE DRAWING

Before you start drawing, put all the materials and equipment you may need, such as pencils, sandpaper pad, erasers, triangles and curves within easy reach. If you are not using a lead holder, you would do well to sharpen a number of pencils so that you will not have to stop work often later to sharpen pencils.

You can do better work in pencil if your drawing board is covered with a drawing board covering as described in chapter 3 or a sheet of firm paper which serves as a backing for your drawing sheet. When you mount this covering sheet on your drawing board, be sure it does not stick out over the edge on which your T-square slides nor interfere in any way with the free action of the T-square.

Keeping a Clean Drawing

When you start a drawing, remember that there is no excuse for sloppy work and dirty drawings. To keep your drawing clean, you need only observe a few simple rules as you work.

1. Before you begin a drawing, dust your T-square, especially the under side of the blade, dust your drawing board, and wipe off your instruments.
2. After any erasure, dust the eraser crumbs from the board and wipe the under side of the T-square. These crumbs may become charged with electricity and cling to surfaces, deflecting the pencil and keeping the T-square or the triangles from lying flat on the paper.
3. Never use a lead pencil softer than a 2H on a mechanical drawing, because soft leads smudge easily.
4. Keep your hands clean.
5. To protect a drawing from dust or injury when you are not working on it, cover it with a cloth or a sheet of clean paper.

Drawing Sheet Sizes

In the Navy, engineering drawings are made in certain standard sizes, which are given in Military Standard Drawing Sizes and Formats, MIL-STD-2C. Each of these sizes is designated by a letter. Table 4-1 lists these sizes by letter. The size of the sheet you use for each drawing will probably be governed by drafting room practice in any command to which you are assigned.

Drawing Sheet Format

The drawing sheet format has been standardized, as well as the size. The distance between the border line which you draw and the actual cut line or margin of the finished drawing may vary a specified amount, depending on whether

Table 4-1.—Finished format sizes (inches).

FLAT SIZES				ROLL SIZES				
SIZE DES (LTR)	X (WIDTH)	Y (LENGTH)	Z (MARGIN)	SIZE DES (LTR)	X (WIDTH)	Y MIN (LENGTH)	Y MAX (LENGTH)	Z (MARGIN)
A(HORIZ)	8.50	11	.25&.38*	G	11	42	144	.38
A(VERT)	11	8.50	.25&.38*	H	28	48	144	.50
B	11	17	.38	J	34	48	144	.50
C	17	22	.50	K	40	48	144	.50
D	22	34	.50					
E	34	44	.50					
F	28	40	.50					

*HORIZONTAL MARGINS .38-INCH, VERTICAL MARGIN .25-INCH, SEE FIGS. 1 & 2

the drawing is to be bound. There is a specified place for the title block, the revision block, and the drawing number which is entered in the official records and which is used in filing. The dimensions of the margins and the various blocks are specified in detail in MIL-STD-2C. Figure 4-1 is typical of the drawings in MIL-STD-2C. In figure 4-1 the letters A through N refer to the following:

A — Record information block
B — Drawing title
C — Design activity identification
D — Design activity approval
E — Approval by activity other than design activity
F — Code identification number
G — Drawing size
H — Drawing number
J — Scale
K — Reference to a specification or report, etc.
L — Multisheet numbers
M — Dimensional notes
N — Material, finish, treatment, etc.

On some drawings, it is necessary to add other elements to the format, such as a block for dimension notes, a block for the description

of material used (bill of material), or a usage block for identifying elements in the drawing with other drawings containing these same elements by drawing numbers. There may also be a block for a complete material record or list and a block for listing physical properties. The security classification block should be included only on those drawings that are classified as Top Secret, Secret, or Confidential. The type and number of these special blocks depends on the purpose of the drawing. MIL-STD-7A lists the definitions and requirements for 28 different types of engineering drawings and shows a sample drawing of each type. Examples of the different types of drawings are: assembly drawing, control drawing, detail drawing, diagram drawing, erection drawing, installation drawing, and matched parts drawing.

In some drafting rooms, the work is so standardized that the drawing sheets used are printed with the border line, the necessary blocks, and even some of the lettering. This saves the individual draftsman the time he would spend laying out the format of a sheet. In other places, each drawing is so different that it requires a different format, and the draftsman must be prepared to execute the necessary format.

Fastening the Drawing Sheet

Fastening a drawing sheet to the drawing board seems like a very simple operation. However, you will find that unless you do it properly, a perfectly smooth, flat surface on which to draw is difficult to obtain. To properly

Figure 4-1.—Horizontal format for A size drawings.

fasten the drawing sheet to the board, follow these steps:

1. Wipe the drawing board and T-square free of all dust.
2. Place the paper in position near the upper left hand corner of the board as shown in figure 4-2. See that the upper edge of the paper is parallel with the upper edge of the board.
3. Place the T-square in position with its head held firmly against the left edge of the board.

Figure 4-2.—Fastening the drawing sheet.

4. Place tape lightly in the upper left hand corner of the paper.
5. With your left hand, slide the head of the T-square into position. Make the top edge of the paper parallel with the top edge of the T-square.
6. With the palm of your hand stroke the paper so that it adheres smoothly to the board, working from the upper left hand corner to the lower right hand corner. Then place tape on the lower right hand corner.
7. Now stroke the paper from the middle of the sheet to the upper right hand corner and place tape there.
8. Test the position of the paper again.
9. Finally, stroke the paper from the middle of the sheet to the lower left hand corner and press tape down firmly.
10. Be sure that all the tape has been pressed down firmly so that the T-square can be moved easily over it.

Order of Penciling

When your paper is firmly mounted on the board, draw the cutting line, or margin line, to the standard size which has been selected for the drawing. Then draw the border line, the title block, and any other blocks you may need.

You may find it a help to make freehand sketches on a piece of scratch paper of the various views you expect to show, before you start to lay out your drawing. Then cut them out and place them on the sheet in correct order and approximate location. Don't forget to allow space for notes and dimension lines.

In making a view drawing, follow this order of penciling:

1. Draw all center lines. Symmetrical parts should be marked by center lines. In views that are not symmetrical, select a large plane face as a base line. (See fig. 4-3a.) On the center lines, point off the over-all dimensions.

Figure 4-3.—Order of penciling a drawing.

2. Draw the chief circles, arcs, and fillets. These circles, as shown in figure 4-3b, often project to another view, and if you draw them first you save yourself the trouble of making the measurements for this other view.

3. Draw the principal horizontal and vertical lines in the views. (See fig. 4-3c.)

4. Draw the slant lines. (See fig. 4-3d.)

5. Clean up the drawing, erasing construction lines and any excess lines. (See fig. 4-3e.)

6. Draw extension lines, dimension lines, and leaders. (See fig. 4-3f.)

Precision Drawing

Actually all detail drawings should be made with as great a precision as possible, because a good drawing inspires confidence and the workman using it will be more likely to do good work on the part he makes with the incentive supplied by a good drawing. However, there are certain techniques which are specifically applicable to layouts. For example, layouts should always be made to as large a scale as possible because of the accuracy required.

In order to make the layout lines, you must use a very sharp pencil. Remove the wood until about 1/2 inch of lead is exposed. Grind the lead to a conical point on a sandpaper pad, rotating the pencil as it moves across the pad. In order to keep the lines the same, you will have to continually repoint the lead on the pad as you work. As you draw a line, rotate the pencil slowly about its own axis to prevent the lead from flattening as it wears. Draw the pencil across the paper with a full arm movement. Arm motion is necessary to produce true lines.

Some men feel that when they do a layout, it is better to stand, rather than to sit on a stool. In general your eyes should be directly above the area on the drawing on which you are working.

On layouts, measurements should always be made along a drawn line. For this reason, layout lines are not drawn to a given length, but when the position and direction of such a line has been determined, it is drawn past the point where an intersection or a measured point may be expected to fall. Measurements should be recorded with a needle point. Do not enlarge the holes made, but encircle them with a light freehand line so that they can be found readily.

When you use a compass, it is necessary to use the same lead you use for the other lines on the layout if they are to be the same weight. Instead of using the leads that come with the compass, cut a length of lead from the same type of pencil you are using for the other lines. It will be easier to obtain the same point if you sharpen the lead to a long conical point before you cut it from the pencil.

Figure 4-4.—Sharpening the lead for the compass; avoid the wedge point.

Since it is not possible to rotate the lead in the compass, some provision must be made to keep it from wearing and causing the line to widen as you draw it. This can be done by flattening the side of the lead. A broad wedge shape, however, should be avoided. (See fig. 4-4.) Remember that you will have to keep continually repointing the lead as you work.

FINISHING THE DRAWING

In making a finished drawing for reproduction, it is often wise to follow the drawing procedure just outlined and make a rough but accurate drawing first. Then you can trace a more finished drawing from this. Complete the drawing by lettering dimensions and notes, and hatching any cross sectioning. Finally letter the title, drawing number, and any other information required in the blocks of the drawing format.

If you are required to make a change in a pencil drawing, place a sheet of tracing paper over the drawing sheet and draw your change on it, connecting the lines with enough lines traced from your original drawing to make it easy to position it on the drawing. Then make any erasures necessary on the original drawing and, slipping the piece of paper with the

Figure 12-13.—Types of magnetic focusing.

PERMANENT MAGNET.—Permanent magnet focusing is frequently used in tube structures where the interaction space is short. Extremely powerful magnets are required for this application, and the weight and physical size must not be excessive if the tube is to be used in airborne applications.

PERIODIC PERMANENT MAGNET.—Periodic permanent magnet (PPM) focusing is perhaps the most important new development in the evolution of beam control methods. In this method, small but powerful permanent magnets are placed at regular intervals along the slow wave structure of the tube. As the electron beam travels along the interaction space, it is acted upon by the magnetic fields which periodically focus it into a sharp beam. Figure 12-14 illustrates the construction and arrangement of this type focusing system.

This lightweight focusing method fills a great need in the high power systems where the focusing solenoids formerly required for the high density electron beam were too large and too heavy for many of the airborne and space applications. The tube shown in figure 12-14 (A) is a high power X-band TWT. The tube is a metal-ceramic type using the coupled cavity interaction space (discussed later), and weighing only about 15 pounds complete. Its magnetic structure is composed of round disks represented in the cross section by the black vertical areas at the ends of the interaction structure. These magnets are separated by the lighter-colored iron pole pieces, which not only act as magnet separators but also form the interaction structures of the tube.

A helix type TWT using PPM focusing is shown in (B) of figure 12-14.

ELECTROSTATIC.—Electrostatic focusing systems have been used with low power and medium power traveling wave tubes, but some difficulty has been encountered at the high power levels. The electrostatic focusing system requires no magnetic field, and it is considered practical to make it even lighter and smaller than the PPM focusing system. However, in the present state of development, it has not yet reached that point.

Slow Wave Circuits

Basically, there are two types of slow wave circuits used in traveling wave tubes. These are the HELIX and the FILTER TYPE. Each of these types has several variations, and each has its advantages and disadvantages. The particular circuit used is determined by the function of the tube and its associated circuitry.

THE HELIX CIRCUIT.—The helix circuit gets its name from the fact that the structure which comprises the slow wave circuit is a coil of wire wound in the shape of a helix, or coil spring. The helix is considered to be the most efficient slow wave circuit for TWT applications. It is capable of producing wider bandwidths than any of the newer versions, but its use is limited by power output restrictions.

The helix is normally made of tungsten or molybdenum, and is wound to extremely accurate dimensions. The fields associated with

984

prefer to ink all horizontal lines, shifting the set of the ruling pen. Others prefer to ink first all the horizontal lines of one weight, then all the horizontal lines of another weight and so forth. Still others prefer to ink the horizontal visual lines as shown in figure 4-7b and go on to ink other visual lines before inking lines of any other weight.

3. Next ink vertical lines, as shown in figure 4-7c.

4. Ink slant lines as systematically as possible. (See fig. 4-7d.)

5. If only visual lines have been inked first, ink other line weights in the same order, including the cross hatching. (See fig. 4-7e.)

6. Finish the drawing by inking all lettering. (See fig. 4-7f.)

Tracing on Cloth

If you are assigned to make an ink tracing on tracing cloth, first check carefully for accuracy the pencil drawing from which you are to make the tracing. Errors in ink on tracing cloth are hard to erase. Since tracing cloth is not completely transparent, you may go over the lines of the pencil drawing with an H pencil to darken them and save yourself eyestrain. Use a needle point to prick the centers of all circles and arcs or draw a small dark circle around the centers. This makes it possible for you to see the centers through the cloth.

On the dull surface of tracing cloth as it comes from the manufacturer, there is a greasy film that repels ink. Remove this film by dusting

Figure 4-8.—Line characteristics and conventions.

a prepared powder, called pounce, on the cloth and rubbing it in with a cloth or with your hand. After the excess pounce has been brushed off, the cloth will take ink.

Do not use water on tracing cloth, and be sure the cloth is kept in a dry place. Since the preparation used to surface the cloth has a starch base, water will destroy the surfacing of tracing cloth and wash out the drawing.

Order of Tracing on Cloth

In tracing the order of inking previously discussed is followed, with one important exception. Since tracing cloth changes shape with changing atmospheric conditions, ink only a section of the drawing which you can finish at one sitting. Do not ink the circles for the entire sheet if you can finish only part of it during the day. If you ink all the circles, you may find that the circles have shifted slightly from their centers by the next morning.

Erasures on Tracing Cloth

Use an ink eraser to erase errors in ink lines on tracing cloth. It requires skill to make

Figure 4-8.—Line characteristics and conventions—continued.

an erasure without laying bare the threads of the cloth. If the threads are laid bare, fresh ink from ink lines drawn over the threads will spread into them just as ink spreads in any cloth, and an ugly blot, impossible to erase, will be formed.

When threads are laid bare, they have to be especially treated before ink lines can be drawn over them. Soapstone is used to resurface the threads. The soapstone can be rubbed on directly, or powdered soapstone can be scraped on with a knife. Rub it in with your finger and polish it briskly with the back of a fingernail.

Do not use a knife to cut out an error if you are planning to ink over the spot. However, after a drawing has been finished, you may use a very sharp knife to cut off excess lines.

Phototracings

In the last few years, more and more drafting rooms have adopted the practice of making their finished drawings in pencil. This has been made possible by the use of phototracings and other methods of making prints directly from pencil drawings. A phototracing, as its name suggests, is a photographic reproduction of a drawing on a sensitized tracing cloth. A negative is made photographically from the original drawing. From this negative, the positive print is made on the cloth by a contact printing process. Usually no more than one of these is made, and it is marked as the master drawing and kept in the files, while the original drawing is destroyed. From a phototracing, blueprints, vandykes, and other duplicates can be made, just as if the phototracing were an ink tracing on tracing cloth.

The use of phototracings has a great many advantages. A phototracing looks like an ink tracing. The cloth has a gelatine backing which makes it more resistant to moisture and longer wearing than tracing cloth. Since making an ink tracing on cloth sometimes takes weeks of a draftsman's time, the phototracing is a great timesaver. The elimination of ink tracing in many drafting rooms also eliminates a long apprentice-training period. Furthermore, a phototracing can very easily be erased and redrawn without damage to the cloth.

However, since the sensitized cloth is commercially prepared by a number of companies, a sample from any single company should be tested before the cloth is used for reproducing drawings. Poor phototracing cloth will stretch or shrink out of shape in the drying process and drawings reproduced on such cloth will become badly distorted.

To erase the lines of a phototracing, use a wet ink eraser. Then you can redraw a portion of the drawing just as if you were working on ordinary tracing cloth but without worrying about exposed threads.

The use of phototracings has made the technique of pencil drawing far more important. A pencil drawing must be good if a good phototracing is to be made from it, and even a good drawing will sometimes reproduce with a few uneven lines or indistinct details.

Touch up a phototracing as you would ink a drawing, following the procedures under the section on order of inking. Touching up a phototracing is never so arduous as making a complete tracing on tracing paper or cloth.

Working on Film

Drafting film may be used for pencil drawings, inked pencil drawings, tracings, or phototracings. Regular pencil smudges more easily on film than it does on paper or pencil cloth; use a harder pencil than usual or use the special leads described in chapter 3.

The order of penciling and inking on film is the same as that previously described for paper. The warning concerning the shape-changing characteristic of paper and, especially, cloth, may be disregarded when you are working on film because the film is exceptionally stable.

Film prepared as an original drafting medium has excellent erasability both for pencil and ink. Phototracings or other types of duplicate originals made on film present a different problem, however. It is difficult to erase duplicated lines without removing the photographic or other type of emulsion from the film, and, as indicated in chapter 3, the raw Mylar is not a good drawing surface—it is difficult to get the pencil or ink to "take" on the raw film. Therefore, if extensive revisions must be made to a phototracing, you may use the following procedure: erase or cut out or have the reproduction people block out the area to be removed; then have a new phototracing made of the drawing; then do your revisions on the new phototracing which will have a usable emulsion over the plastic.

LINE CONVENTIONS

In drawing an object, a draftsman not only arranges the different views in a certain manner, but he also uses different types of lines to convey information. Line characteristics, such as width, breaks in the line, and zigzags, have meaning. Figure 4-8 shows the different types of lines which should be used on engineering drawings as they are given in MIL-STD-1B.

Types of Lines

Often the first lines a draftsman draws on his drawing sheet are the center lines of the views. Center lines are composed of long and short dashes, alternately and evenly spaced, with a long dash at each end. They are used to indicate the center of a symmetrical object. A base line instead of a center line is used for an unsymmetrical view. A center line is also used to indicate the center of a circle or arc on a view. (See fig. 4-9.)

Figure 4-9.—Use of center lines.

A very short center line may be drawn as a single dash if there is no possibility of confusing it with other lines. Center lines may also be used to indicate the travel of a moving center.

The visible lines of the views are drawn as solid, thick lines. These include not only the outlines of the view, but lines defining edges which are visible within the view. (See fig. 4-10.)

Figure 4-10.—Use of visible lines.

Hidden lines are drawn with short dashes and are used to show the hidden features of an object. A hidden line should begin with a dash in contact with the line from which it starts, except when it is the continuation of an unbroken line. (See fig. 4-11.)

Figure 4-11.—Use of hidden lines.

Extension lines are used to extend dimensions beyond the outline of a view so that they can be read easily. These thin, unbroken lines are started about 1/16 of an inch from the outline of the object and extend about 1/8 of an inch beyond the dimension line. They are drawn parallel to each other and perpendicular to the distance to be shown. (See fig. 4-12.)

Figure 4-12.—Use of extension lines.

As far as practicable, avoid drawing dimension lines directly to the outline of an object. When it is necessary for extension lines to cross each other, they should be broken, as shown in figure 4-13.

A dimension line, terminating at either end in a long, pointed arrowhead, is inserted between each pair of extension lines. It is a thin line, and except in structural drafting, it is usually broken to provide a space for the dimension numerals. Occasionally, when the radius of an arc is to be indicated, there is an arrow at only the end of the line which touches the arc. The other end, without an arrow, terminates at the point used as the center in drawing the arc.

A leader is a line with an arrowhead which touches the surface to which the leader refers

Figure 4-13.—Breaking extension lines and leaders at points of intersection.

or an extension line to that surface. Leaders are used to connect numbers, references, or notes to the appropriate surface on the drawing. These lines are drawn at an angle to show their difference from other lines. Leaders should terminate at the lettering end with a line approximately 1/8 inch long which is parallel to the construction lines of the lettering and centered on the first line of letters. (See fig. 4-14.)

Figure 4-14.—A leader.

Break lines may be used to save space when an extended part of an object has the same continuous shape and size. For instance, they may be used when the details of a piping system are to be shown. Drawing space can be saved by "breaking" the line representing a pipe and leaving an unimportant part out of the drawing. Long break lines are drawn as thin, zigzag lines; short break lines are drawn as thick, wavy lines.

For drawings made to a large scale, special conventions are used that apply to drawing breaks in such things as metal rods, tubes, or bars. The methods of drawing these breaks are shown in figure 4-15.

Cutting plane lines are used to indicate a plane or planes in which a sectional view is taken. For a more complete discussion and illustrations of the use of these lines, see "Sectioning Techniques" in this chapter.

Figure 4-15.—Special breaks.

Viewing plane lines are used to indicate the plane or planes from which a surface or several surfaces are viewed.

Phantom lines are used to show the alternate position of movable parts or repeated details, or the position of some related part that is absent. (See fig. 4-16.)

Figure 4-16.—Use of phantom lines.

Line Widths

The widths of the various lines used in making a drawing are important in interpreting

the drawing. MIL-STD-1B states that in inked drawings three widths of line should be used; thin, medium, and thick. The actual width of each type of line should be governed by the size and the style of the drawing.

On pencil drawings, the width of lines cannot be controlled as well as can the width of lines drawn with a ruling pen and ink. Pencil lines should be opaque and of uniform width throughout their length. Cutting plane and viewing plane lines should still be the thickest lines on the drawing. Lines used for outlines and other visible lines should be thick enough so that they can be differentiated from hidden, extension, dimension, or center lines.

Figure 4-17.—Method of drawing an arrowhead.

Drawing the Arrowhead

The arrowhead on a dimension or leader line is an important detail of a drawing. If these arrowheads are sloppily drawn and vary in size, the drawing will not look finished and professional. The size of the arrowhead used on a drawing may vary with the size of the drawing, but all arrowheads on a single drawing should be the same size, except occasionally when a space is very restricted.

The arrowheads used on Navy drawings are usually solid, or filled in, and are between one-eighth and one-fourth of an inch long, with the length about three times the spread. (See fig. 4-17.) When many arrowheads of one size are to be drawn, it may save time to cut a template, or pattern, of the arrowhead in a sheet of plastic. Such a template is easy to use when the drawing is in pencil. When you are using ink, much more care is necessary to keep the ink from running under the edge of the plastic and spoiling the drawing.

Figure 4-18.—Transferring an angle.

With a little practice, you can learn to make good arrowheads freehand. First, define the length of the arrowhead with a short stroke, as shown in figure 4-17a. Draw the sides of the arrowhead as shown in figure 4-17b and c. Then fill in with ink the area enclosed by the lines, as shown in figure 4-17d.

GEOMETRIC CONSTRUCTIONS

CONSTRUCTIONS INVOLVING ANGLES

Transferring an Angle

There is a geometric construction for laying off, on another part of the same drawing or on a different drawing, an angle equal in size to one which is already drawn. This procedure (which is called transferring the angle) is illustrated in figure 4-18. Here the draftsman desired to lay off from O' a line which would make an angle with B'O' equal to angle BOA. He drew an arc through OB and OA, with O as a center, as shown in figure 4-18(A). He then drew an arc of the same radius from B'O', with O' as a center, as shown in figure 4-18(B). Next he measured the length of the arc between OB and OA and laid off the same length on the arc from B'O'. A line from O' through the end of this arc made an angle with B'O' equal to angle BOA.

Bisecting an Angle

To bisect an angle means to divide it in half. If you know the size of an angle, you can bisect it by simply dividing the size by 2 and laying off the result on a protractor. To bisect a 45-degree angle, you would simply lay off 22.5° on the protractor.

Figure 4-19.—Bisecting an angle.

Geometric construction for bisecting an angle is shown in figure 4-19. To bisect the angle AOB, the draftsman first laid off equal lengths from O on OA and OB (fig. 4-19A). From the ends of these lengths, he laid off equal, intersecting arcs (fig. 4-19B). A line from O through the point of intersection of the arcs bisects angle AOB (fig. 4-19C).

CONSTRUCTIONS INVOLVING STRAIGHT LINES

Parallel Lines

In the preceding chapter you learned how to draw a line through a given point, parallel to another line, by the use of a straightedge and a sliding triangle. Another method of solving this problem is illustrated in figure 4-20. To draw a line through C parallel to AB, place the needlepoint of a compass at any point D on AB, and strike arcs through C and through AB.

Figure 4-20.—Drawing a line through a given point, parallel to another line.

Shift the needlepoint of the compass to point of intersection E, and strike an arc of the same radius through AB, intersecting AB at D. Set compass or dividers to the length of the arc CE, and lay off the same length on the arc from D; this is DF in figure 4-20. A line A'B', drawn through F and C, is parallel to AB.

Figure 4-21 shows another solution to the problem of drawing one line parallel to another; this one is used when the second line is to be drawn at a given distance from the first. To draw a line parallel to AB, at a distance from AB equal to CD, set the compass to the length of CD and from any points E and F on AB strike two arcs. A line A'B', drawn tangent to (just touching, as shown) the arcs is parallel to AB, at a distance equal to CD.

Figure 4-21.—Drawing parallel line at a given distance from another line.

Perpendiculars

In the preceding chapter you learned how to draw a line perpendicular to another by the use of a straightedge and a sliding triangle. Other methods of solving this problem are as follows.

Figure 4-22 illustrates a method of dropping a perpendicular from a given point to a line. To drop a perpendicular from point P to AB, set the needlepoint of a compass at P and strike an arc intersecting AB at C and D. With C and D as centers and any convenient radius larger than one-half of CD, strike arcs intersecting at E. A line from P through E is perpendicular to AB.

Figure 4-22.—Dropping a perpendicular from a given point to a line.

Figure 4-23 illustrates a method of erecting a perpendicular from a given point on a line. To erect a perpendicular from point P on line AB, set a compass to any convenient radius and strike arcs intersecting AB at C and D. With C and D as centers and any convenient radius larger than CP, strike arcs intersecting at E. A line from P through E is perpendicular to AB.

Bisecting a Line

A line can be bisected by trial-and-error with the dividers—that is, by setting the dividers to various spreads until you get a spread which comes to exactly one-half of the length of the line.

Another solution of the problem of bisecting a line is illustrated in figure 4-24. To bisect the line AB, use the ends of the line as centers,

Figure 4-23.—Erecting a perpendicular from a given point on a line.

Figure 4-24.—Bisecting a line.

set a compass to any convenient radius which is more than one-half the length of AB, and strike arcs intersecting at C and D. A line drawn through C and D bisects AB.

More Than Two Equal Parts

A line may be divided into more than two equal parts by trial-and-error with the dividers, as described for bisecting a line. Another method of dividing a line into any number of equal parts is illustrated in figure 4-25. To divide AB into 10 equal parts, draw random line CB from B, at a convenient acute angle to AB. Set a compass to a spread less than one-tenth of the length of CB, and lay off this spread 10 times from B on CB. Project the intermediate points of intersection on CB to AB by lines parallel to the line between the 10th point of intersection and A. The projected points of intersection divide AB into 10 equal parts.

Figure 4-26 shows how you can use a scale of convenient size to lay off the equal intervals on the random line.

Proportional Parts

Figure 4-27 illustrates a method of dividing a line into parts bearing a given proportion. The problem here is to divide the line AB into parts which are proportional as 2:3:4. Lay off a random line CB from B, at a convenient acute angle to AB; set a compass to a convenient spread, and lay off this spread on CB a number of times equal to the sum of the figures in the proportion. This sum is 9 (2 + 3 + 4). Use a straightedge and sliding triangle to project the 2nd and the 5th intercepts on CB to AB by lines parallel to 9A. These projected intercepts divide AB into segments which are proportional as 2:3:4. Here again you could use a scale of convenient size to lay off the equal intervals on CB.

Parts With a Given Ratio

You may be required to divide a line into parts in such a manner that the ratio between the whole line and one of its segments is the same as that between two other lines. A solu-

Figure 4-25.—Dividing a line into any number of equal parts.

Figure 4-26.—Using a scale to lay off equal intervals on random line.

Figure 4-27.—Dividing a line into proportional parts.

tion to this problem is illustrated in figure 4-28. Here it is required that AB be divided so that the ratio between AB and a segment of AB is the same as the ratio between CD and EF. From A draw a random line AG, at a convenient acute angle to A, and lay off AH equal to EF and AI equal to CD. Use a straightedge and sliding triangle to project H to AB on a line parallel to the line from I to B. The ratio of AB to AJ is the same as the ratio of CD to EF—that is, (AB:AJ):(CD:EF).

CONSTRUCTIONS INVOLVING PLANE FIGURES

Triangle: Three Sides Given

To draw a triangle with three sides given, draw a straight line AB, equal in length to one of the given sides. With A as a center, strike an arc with radius equal to the given length of the second side; with B as a center, strike an intersecting arc with radius equal to the length of the third side. Draw lines from A and B to the point of intersection of the arcs.

Right Triangle: Hypotenuse and One Other Side Given

Figure 4-29 illustrates a method of drawing a right triangle when the hypotenuse and one of the other sides are given. The line labeled H in the figure is the given hypotenuse; the line labeled S is the given shorter side. To construct the triangle, draw AB equal to H. Locate the center of AB, by bisecting AB, and with one-half of AB as a radius, draw a semicircle around AB as shown. Set the compass to the length of S and with A as a center strike an arc intersecting the semicircle at C. Draw AC and CB.

Figure 4-28.—Dividing a line into parts with a given ratio.

Figure 4-29.—Constructing a right triangle with hypotenuse and one of the other sides given.

Figure 12-14.—TWT's using PPM focusing system.

the "slow waves" they carry must travel at the same axial speed as the stream of electrons emitted from the cathode. For example, in a 1,500-volt electron beam, the axial speed at which the electrons travel is one-thirteenth the speed of light. Since the RF signal is carried along the wire from which the helix is wound at about the speed of light, the resulting linear ratio of the helix length to the beam length must be 13:1 in this example.

A number of configurations using the basic helix structure have been tested in an attempt to increase the power output capabilities of the tube. The CONTRAWOUND HELIX structure uses two helices wound in opposite directions, and effectively increases the power output capability of the tube to a moderate degree. The RING-BAR shown in figure 12-15 is one version of the contrawound helix.

One disadvantage of the helix circuit has been the fragile glass vacuum envelope which encloses the tube parts; however, such glass structures are sufficiently well supported to withstand almost any environment and can tolerate very high shock and loads. Recently a means of adapting metal and ceramic materials for use in the place of glass in the manufacture of TWT's has been developed. These tubes

Equilateral Triangle: Length of Side Given

To construct an equilateral triangle when the length of a side is given, you can follow the method previously described for constructing a triangle when the length of each side is given. As you know, the sides of an equilateral triangle are equal in length.

You also know that in an equilateral triangle each of the angles measures 60°. You can apply this fact to the problem of constructing an equilateral triangle when the length of a side is given by following the procedure illustrated in figure 4-30. Draw one side, AB, to the correct given length, and use a straightedge and a sliding 30-60 degree triangle to erect lines from A and B at 60° to AB.

Figure 4-30.—Equilateral triangle with length of side given.

Equilateral Triangle in Given Circumscribed Circle

A circumscribed plane figure is one which encloses another figure. If a triangle (for example) encloses a circle, the triangle is circumscribed; but if the circle encloses the triangle, the circle is circumscribed. To be circumscribed in the true sense, the circumscribed figure must be in contact, all the way around, with the outlying points of the enclosed figure. A plane figure which is enclosed by a circumscribed figure is called an inscribed figure.

Figure 4-31 shows you how to draw an equilateral triangle within a given circumscribed circle. Draw a vertical center line through the circle, intersecting the circumference at A and B. With B as a center and the radius of the circle as a radius strike arcs intersecting the circumference at C and D. A, C, and D now divide the circle into 3 equal arcs. Lines connecting A, C, and D will form an equilateral triangle. If you desire to have the triangle inverted (pointing down instead of up), use A as a center for striking the arcs, and connect the arc intercepts with B.

Figure 4-31.—Equilateral triangle in given circumscribed circle.

Equilateral Triangle on a Given Inscribed Circle

Figure 4-32 illustrates one method of circumscribing an equilateral triangle on a given inscribed circle. Draw AB parallel to the horizontal center line of the circle and tangent

Figure 4-32.—Equilateral triangle on given inscribed circle: one method.

Figure 4-33.—Equilateral triangle on given inscribed circle: another method.

to the circumference. Then use a straightedge and sliding 30-60 degree triangle, as illustrated in figure 4-30, to draw AC and CB, tangent to the circumference of the circle and at 60° to AB.

Another method of circumscribing an equilateral triangle on a given inscribed circle is shown in figure 4-33. Divide the circumference of the circle into three equal arcs, as shown in figure 4-31. Another way to do this is to draw two radii, OC and OB, at 30° from the horizontal center line as shown in figure 4-33. The third intercept is the vertical center line intercept at A. You now have three radii: OA, OC, and OB. Draw each side of the triangle tangent to the circumference of the circle and perpendicular to the relevant radius.

Figure 4-34.—Constructing a square by use of diagonals.

Rectangle: Given Length and Width

To construct a rectangle with given length and width, draw a horizontal line AB with the T-square, equal to the given length. With T-square and triangle, erect perpendiculars from A and B, equal to the given width; and connect the ends of the perpendiculars.

Square: Given Length of Side

You can construct a square with a given length of side by the method described for constructing a rectangle. Another method is illustrated in figure 4-34. Draw a horizontal line AB with the T-square, equal to the given

Figure 4-35.—Square with given length of diagonal.

length of side. With the T-square and a 45-degree triangle, draw diagonals from A and B at 45°. Erect perpendiculars from A and B, intersecting the diagonals, and connect the points of intersection.

Square: Given Length of Diagonal

Figure 4-35 illustrates a method of constructing a square with a given length of diagonal. Draw a horizontal line AB, equal in length to the given length of diagonal; let this be one diagonal of the square. Locate O, at the center of AB, and lay off CD through O, perpendicular to and slightly longer than AB. Use a T-square and 45-degree triangle to draw AF and EB at 45° to AB. Connect AE and FB.

Square in Given Circumscribed Circle

Figure 4-36 shows a method of drawing a square in a given circumscribed circle. Draw the diameters AB and CD at right angles to each other, and connect the points where the diameters intercept the circumference of the circle.

Figure 4-36.—Square in given circumscribed circle.

Square Circumscribed on Given Inscribed Circle

Figure 4-37 illustrates a method of circumscribing a square on a given inscribed circle. Draw the diameters AB and CD at right angles to each other. Then draw each side of the square tangent to the point where a diameter intersects the circumference of the circle, and perpendicular to the diameter.

Figure 4-37.—Square on given inscribed circle.

Any Regular Polygon by Trial-and-Error

A 5-sided polygon is called a pentagon, a 6-sided polygon a hexagon, a 7-sided polygon a heptagon, and an 8-sided polygon an octagon. There are names for polygons with more than 8 sides, but you seldom deal with any of these and their names are not important.

You can draw any regular polygon in a given circle by trial-and-error with compass or dividers, as illustrated in figure 4-38. To draw a 9-sided regular polygon in a given circumscribed circle, draw the circle, divide the circumference by trial-and-error with the compass or dividers into 9 equal segments, and connect the points of intersection. To get a trial spread to start with, compute the circumference of the

Figure 4-38.—Any regular polygon by trial-and-error with compass or dividers.

circle and divide it by 9. Suppose for example, that the diameter of the circle shown in figure 4-38 is 4 in. The circumference is (4 x 3.14), or 12.56 in. One-ninth of this is just a shade less than 1.4 in. Set your compass to this on the 10 scale of your chain scale, and use that as your first trial spread.

Any Regular Polygon, Given Length of Side

Figure 4-39 illustrates a method of drawing any regular polygon with a given length of side. To draw a 9-sided regular polygon with length of side equal to AB, first extend AB to C, making CA equal to AB. With A as a center and

AB (or CA) as a radius, draw a semicircle as shown. Divide the semicircle into 9 equal segments from C to B, and draw radii from A to the points of intersection. The radius A2 is a second side of the polygon.

Draw a circle through points A, B, and D. You do this by erecting perpendicular bisectors from DA and AB; the point of intersection of the bisectors is the center of the circle.

This circle is the circumscribed circle of the polygon. To draw the remaining sides of the polygon, extend the radii from the semicircle as shown, and connect the points where these radii intersect the circumscribed circle.

Figure 4-39.—Any regular polygon with given length of side.

Regular Pentagon in Given Circumscribed Circle

Besides the methods described for drawing any regular polygon there are particular methods for drawing a regular pentagon, hexagon, or octagon.

Figure 4-40 illustrates a method of drawing a regular pentagon in a given circumscribed circle. First draw a horizontal diameter AB and a vertical diameter CD. Locate E, the midpoint of the radius OB. Set a compass to the spread between E and C, and with E as a center strike the arc CF. Set the compass to the spread between C and F, and with C as a center strike the arc GF. The straight line G to C is one side of the pentagon. Set the compass to the length of GC, lay off this spread from C around the circle, and connect the points of intersection.

Figure 4-40.—Regular pentagon.

Regular Hexagon in Given Circumscribed Circle

A great many bolt heads and nuts are hexagonal (6-sided) in shape; you will therefore be often required to draw a regular hexagon.

Figure 4-41 illustrates a method of drawing a regular hexagon when the circumscribed circle is given. The diameter of the circumscribed circle has the same length as the long diameter of the hexagon. The radius of the circumscribed

Figure 4-41.—Regular hexagon in given circumscribed circle: one method.

circle (or one-half the long diameter of the hexagon) is equal in length to the length of a side. Lay off the horizontal diameter AB, set a compass to one-half of this or OB, lay off this spread all the way around the circle, and connect the points of intersection.

Figure 4-42 illustrates another method of drawing a regular hexagon in a given circumscribed circle. Draw the vertical diameter AB, and use a T-square and 30-60 degree triangle to draw BC to 30° to the horizontal. Set a compass to BC, lay off this spread around the circle, and connect the points of intersection.

Figure 4-42.—Regular hexagon in given circumscribed circle: another method.

Figure 4-43.—Regular hexagon on given inscribed circle.

Regular Hexagon in Given Inscribed Circle

Figure 4-43 shows a method of drawing a regular hexagon around a given inscribed circle. Draw the horizontal diameter AB and the vertical center line as shown. Draw perpendiculars to AB at A and B, tangent to the circle. Use a T-square and 30-60 degree triangle to draw lines at 30° to the horizontal between the perpendiculars and the vertical center line, tangent to the circle.

Regular Octagon in Given Circumscribed Circle

Figure 4-44 shows a method of drawing an octagon in a given circumscribed circle. Draw the horizontal diameter AB and the vertical diameter CD. Use the T-square and 45-degree

Figure 4.44.—Regular octagon in given circumscribed circle.

triangle to draw additional diameters EF and GH at 45° to the horizontal. Connect the points where the diameters intersect the circle.

Regular Octagon on Given Inscribed Circle

Figure 4-45 shows a method of drawing an octagon around a given inscribed circle. Draw the horizontal diameter AB and the vertical diameter CD. Draw perpendiculars at A, B, C, D, tangent to the circle. Then use a T-square

Figure 4-45.—Regular octagon on given inscribed circle.

and triangle to draw lines at 45° to the horizontal, tangent to the circle and intersecting the perpendiculars.

CONSTRUCTIONS INVOLVING CIRCULAR CURVES

Circle Passing Through Three Points

In figure 4-46, the problem is to draw a circle (or a circular arc) which passes through points A, B, and C. Connect the points by lines, and erect perpendicular bisectors from the lines as shown. The point of intersection of the perpendicular bisectors is the center of the circle or arc which passes through the points.

Figure 4-46.—Circle or arc passing through three points.

Line Tangent to a Circle at a Given Point

A line which is tangent to a circle at a given point is perpendicular to the radius which intersects the point. It follows that one method of drawing a line tangent to a circle at a given point is to draw the radius which intersects the point and then draw the line touching the circle at the point of intersection and perpendicular to the radius.

Another method is shown in figure 4-47. To draw a line tangent to the circle at P, set a compass to the radius of the circle and, with

Figure 4-47.—Line tangent to given point on a circle.

P as a center, strike an arc which intersects the circle at A. With the compass still set to the radius of the circle, use A as a center and strike an arc which intersects the first arc at B. With B as a center and the compass still set to the radius of the circle, strike another arc. A line through the point of intersection of the last-drawn arcs and through P is tangent to the circle at P.

Circular Arc of Given Radius Tangent to Two Straight Lines

The problem of drawing a fillet or a round (explained in a previous section) comprises the problem of drawing a circular arc of given radius which is tangent to two non-parallel lines.

Figure 4-48.—Circular arc tangent to two lines which form a right angle.

Figure 4-50.—Circular arc tangent to a straight line and to another circular arc.

Figure 4-48 shows a method which can be used when the two nonparallel lines form a right angle. AB is the given radius of the arc. Set a compass to this radius, and with the point of intersection of the lines as a center, strike an arc which intersects the lines at C and D. With C and D as centers and the same radius, strike intersecting arcs as shown. The point of intersection of these arcs is the center of the circle of which an arc of the given radius is tangent to the lines.

Figure 4-49 shows a method which can be used regardless of the size of the angle formed by the lines. Once again AB is the given radius of the arc, and the problem is to draw an arc of that radius, tangent to CD and EF. Draw GH parallel to CD, and at a distance from CD equal to the given radius of the arc. Draw IJ parallel to EF, also at a distance equal to the given radius of the arc. The point of intersection between GH and IJ is the center of the circle of which an arc of the given radius is tangent to CD and EF.

Circular Arc of Given Radius Tangent to Straight Line and to Another Circular Arc

The problem in figure 4-50 is to draw a circular arc with radius equal to AB, tangent to the circular arc CD and to the straight line EF. Set a compass to a radius equal to the radius of the circular arc CD plus the given radius AB (this radius is indicated by the dotted line shown), and with O as a center strike the

Figure 4-49.—Circular arc tangent to two lines which form any angle.

Figure 4-51.—Circular arc tangent to two other circular arcs.

arc GH. Draw a line IJ parallel to EF, at a distance from EF equal to AB. The point of intersection between GH and IJ is the center of the circle of which an arc of the given radius is tangent to CD and EF.

Circular Arc of Given Radius Tangent to Two Other Circular Arcs

The problem in figure 4-51 is to drawn an arc with radius equal to AB, tangent to the circular arcs CD and EF. Set a compass to a spread equal to the radius of CD plus AB (indicated by the left-hand dotted line), and with O as a center strike an arc. Set the compass to a spread equal to the radius of EF plus AB (indicated by the right-hand dotted line), and with O' as a center strike another arc. The point of intersection between these two arcs is the center of the circle of which an arc of given radius is tangent to CD and EF.

In figure 4-51, the circular arcs CD and EF curve in opposite directions. In figure 4-52, the problem is to draw an arc with radius

Figure 4-52.—Circular arc tangent to arcs which curve in the same direction.

equal to AB, tangent to two circular arcs (CD and EF) which curve in the same direction. Set a compass to a radius equal to the radius of CD plus AB, and with O as a center, strike an arc. Set the compass to a radius equal to the radius of EF less AB, and with O' as a center, strike an intersecting arc. The point of intersection between these two arcs is the center of the circle of which an arc of the given radius is tangent to CD and EF.

When a circular arc is tangent to another, it is commonly the case that the two arcs curve

Figure 4-53.—Circular arc tangent to, and enclosing. two other circular arcs.

in opposite directions. However, an arc which is tangent to another may be an arc which curves in the same direction as the other. When this is the case, the tangent arc is said to enclose the other arc.

An arc which is tangent to two others may enclose one or both of the others. In figure 4-53, the problem is to draw a circular arc with radius equal to AB, tangent to, and enclosing, both CD and EF. Set a compass to a radius equal to AB less the radius of CD (indicated by the dotted line from O), and with O as a center, strike an arc. Set the compass to a radius equal to AB less the radius of EF (in-

Figure 4-54.—Circular arc tangent to and enclosing one arc, and tangent to but not enclosing another.

dicated by the dotted line from O'), and with O' as a center, strike an intersecting arc. The point of intersection between these two arcs is the center of a circle of which an arc of given radius is tangent to, and encloses, both CD and EF.

An arc which is tangent to two others may enclose only one of the others. In figure 4-54 the problem is to draw a circular arc with radius equal to AB, tangent to and enclosing CD, and tangent to but not enclosing EF. Set a compass to a radius equal to AB less the radius of CD (indicated by the dotted line from O), and with O as a center, strike an arc. Set

Figure 4-55.—Curve composed of a series of consecutive tangent circular arcs.

the compass to AB plus the radius of EF (as indicated by the dotted line from O'), and with O' as a center, strike an intersecting arc. The point of intersection between the two arcs is the center of a circle of which an arc of the given radius is tangent to and encloses CD, and also tangent to, but does not enclose, EF.

Compound Curve

A curve which is made up of a series of successive tangent circular arcs is called a compound curve. In figure 4-55, the problem is to draw a compound curve passing through given points A, B, C, D, and E. First, connect these points by straight lines; the straight line between each pair of points constitutes the chord of the arc which passes through the points.

Erect a perpendicular bisector from AB, select an appropriate point O_1 on the bisector as a center, and draw the arc AB. From O_1 draw the radius O_1B. From BC erect a perpendicular bisector. The point of intersection (O_2) between this bisector and the radius O_1B is the center of the arc BC. Draw the radius O_2C, and erect a perpendicular bisector from CD. The point of intersection (O_3) between this bisector and the extension of O_2C is the center of the arc CD.

It is obvious that to continue the curve from D to E you must reverse the direction of curvature of the arc. Draw the radius O_3D, and erect a perpendicular bisector from DE on the opposite side of the curve from those previously erected. The point of intersection between this bisector and the extension of O_3D is the center of the arc DE.

Reverse or Ogee Curve

A reverse or ogee curve is a curve composed of two consecutive tangent circular arcs, one of which curves in the opposite direction to the other.

Figure 4-56 illustrates a method of connecting two parallel lines by a reverse curve tangent to the lines. The problem is to draw a reverse curve which is tangent to the upper line at A and to the lower line at B. Connect A and B by a straight line AB. Select a point C on AB, this being the point where you want to have the reverse curve change direction. Erect perpendicular bisectors from BC and CA, and erect perpendiculars from B and A. The points of intersection (O_1 and O_2) between the perpendiculars are the centers of the arcs BC and CA.

Figure 4-57 illustrates a method of drawing a reverse curve tangent to three intersecting straight lines. The problem here is to draw a reverse curve tangent to the three lines which intersect at points A and B. Select on AB a point

Figure 4-56.—Reverse curve connecting and tangent to two parallel lines.

Figure 4-57.—Reverse curve tangent to three intersecting straight lines.

C, this being the point where you want the reverse curve to change direction. Lay off from A a distance equal to AC to establish point D. Erect a perpendicular from D and another from C. The point of intersection of these perpendiculars (O_1) is the center of the arc DC.

Lay off from B a distance equal to CB to establish point E. Erect a perpendicular from E, and extend O_1C to intersect it. The point of intersection (O_2) is the center of the arc CE.

Rectifying a Circular Arc

To rectify a circular arc means to ascertain its straight-line length—that is, to determine what the length of the arc would be if it were converted to a straight line.

Figure 4-58 illustrates a graphic solution called rectifying an arc on its tangent. The problem here is to rectify the arc AB. Draw the radius OB and erect a tangent from B. Draw the chord AB, and extend it to C, making CB equal to one-half of AB. With C as a center and AC as a radius, strike an arc intersecting the tangent at D, DB is very slightly shorter than the arc AB. For an arc which subtends a 45-degree angle, the difference is about 1 unit in 2866 units meaning that if the arc AB were 2866 ft long, DB would be 2865 ft long.

Figure 4-58.—Rectifying a circular arc.

Laying Off a Given Length on a Circular Arc

Figure 4-59 illustrates a method of laying off a given length on a circular arc. The problem is to lay off, on the arc shown in the figure, a length equal to AB. Draw the radius OC, and draw a tangent CD equal to AB. Extend OC to the left to E, making EO twice as long as OC. Connect E and D by a straight line which intersects the arc at F. The arc FC is very slightly shorter than the tangent CD. For a subtended angle of 30° the difference in length would be 1 in 2326, for 45° it would be 1 in 420; and for 60° it would be 1 in 132.

Figure 4-59.—Laying off a given length on a circular arc.

This method can also be used for rectifying a circular arc. It is slightly less accurate than the method illustrated in figure 4-58.

CONSTRUCTIONS INVOLVING NON-CIRCULAR CURVES

The basic uniform noncircular curves are the ellipse, the parabola, and the hyperbola. These curves are called conic sections, because they are curves of the type which would be formed if a cone were cut by planes as illustrated in figure 4-60. The circle (not shown) is also a conic section.

Ellipse by Pin-and-String Method

The dimensions of an ellipse are given in terms of the lengths of the major (longer) and minor (shorter) axis. Figure 4-61 illustrates a method of drawing an ellipse which is called

Figure 12-15.—A contrawound helix.

can withstand higher loads and can be fired at higher temperatures than before; this assures considerably better "cleanup" of undesirable gases trapped in the tube, and improved reliability at higher operating temperatures.

FILTER TYPE CIRCUITS.—The basic helix structure and its major variations have two main limitations when used at high power levels: the inherent tendency to oscillate, and the inability to dissipate the large quantities of heat accumulated. Several versions of the filter type slow wave circuit have shown great promise in overcoming these shortcomings, while maintaining the wide bandwidth of the traveling wave tube.

The simple waveguide is basically a high pass filter. If the waveguide is periodically loaded (loads placed along the guide in such a manner that the wave sees these loads periodically as it travels along the guide), reflections result from the loading devices. Thus, the high pass filter becomes a bandpass filter with specific characteristics which depend on the nature of the periodic loading utilized.

FUNDAMENTAL FORWARD WAVE circuits have been developed in which a disturbance of the basic waveguide mode is introduced at a point where the phase and group velocities of the wave are in the SAME direction. One of these circuits, the CLOVERLEAF (so called because the circuit couplers are connected so as to resemble a four-leaf clover), has achieved up to 2 megawatts peak power at S-band frequencies, over a 10-percent bandwidth, with gains on the order of 20 to 30 decibels.

Another broad group of filter type slow wave circuits, called SPATIAL HARMONIC FILTERS, uses a coaxial mode which is distorted by the waveguide wall. The fundamental wave in these circuits has its phase and group velocities in OPPOSITE directions. Therefore, a harmonic (usually the first) is used. These circuits are used as BACKWARD WAVE AMPLIFIERS or as BACKWARD WAVE OSCILLATORS. Spatial harmonics should not be confused with frequency harmonics. Spatial harmonics are all approximately the same frequency, but are developed at different times as the electron bunch travels through the slow wave structure. Thus, they are related to the periodicity of the slow wave structure.

The SINGLE-SLOT, DOUBLE-SLOT, and DRIFT TUBES are examples of the spatial harmonic circuits. Double-slot TWT's have been built which produce 1 megawatt peak power output over a 9-percent bandwidth, with gains also in the 20- to 30-decibel region.

One of the most significant developments in recent years has been the utilization of basic waveguide mode resonators, coupled together by means of capacitive or inductive apertures, to provide either a fundamental forward or a backward wave circuit. This device is known as the COUPLED CAVITY CIRCUIT. It is also known as a FOLDED WAVEGUIDE circuit, since its structure resembles a waveguide folded in accordion fashion. Figure 12-16 illustrates a cross section view of a high power, coupled cavity tube of the spatial harmonic variety.

Originally these structures provided frequency bandwidths on the order of 10 to 15 percent. Recently, however, means have been developed for increasing the bandwidth of these circuits to 40 percent and more; and tubes utilizing this circuit have produced several hundred kilowatts peak power in the S and X bands, with up to 50 decibels gain.

Another version of the coupled cavity circuit, the interdigital line, has found extensive use in low and medium power amplifiers ranging in power output up to 1 kilowatt peak, with gains of about 30 decibels.

The Collector

The only function of the collector is to dissipate the energy of the electrons in the form of heat as they emerge from the slow wave structure. This is usually accomplished by conduction to a colder outside surface, where the heat is absorbed by circulated air or liquid. The collector size is determined by the method of cooling used and by the amount of energy which must be released.

Figure 4-60.—Conic sections: (A) ellipse; (B) parabola; (C) hyperbola.

Figure 4-61.—Ellipse by pin-and-string method.

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

the pin-and-string method. The problem is to draw an ellipse with major axis AB and minor axis CD. Set a compass to one-half the length of AB, and with C as a center strike arcs intersecting AB at F and F'. Set a common pin at point C, another at F, and a third at F'. Tie the end of a piece of string to the pin at F, pass the string around the pin at C, pull it well taut, and fasten the other end to the pin at F'. Remove the pin at C, place the point of the pencil in the bight of the string, haul out the slack in the string, and draw the ellipse as shown in the third view, keeping the string taut all the way around.

Ellipse by Trammel Method

Another method of drawing an ellipse, called the trammel method, is illustrated in figure 4-62. In this method you plot a series of points along the ellipse by the use of a marked

Figure 4-62.—Ellipse by trammel method.

straightedge called a trammel. A strip of paper, cardboard, or plastic, or the edge of a triangle, will serve the purpose. On the edge of the trammel lay off OE equal to one-half of the minor axis CD and OF equal to one-half of the major axis AB. If the trammel is set on the axes so that E is constantly on the major axis AB and F constantly on the minor axis CD, O will always be on the ellipse, regardless of the angle of the trammel. This being the case, you can use the trammel in the manner illustrated, to plot a series of points along the ellipse. You can then fair a line through the points with a french curve.

Ellipse by Foci Method

Another method of drawing an ellipse is the fOCI method illustrated in figure 4-63. In this method you plot a series of points along the ellipse by drawing a series of intersecting arcs, using two points on the major axis as centers. These points are the fOCI. To locate the foci (F and F' in fig. 4-63), set a compass to one-half of the major axis and, with C as a center, strike arcs intersecting the major axis. Lay off from O toward F a series of at least 5 equal intervals on the major axis. To plot point 1 on the ellipse, set the compass to A1 and with F' as a center strike an arc; then set the compass to B1 and with F as a center, strike an intersecting arc. To plot point 2 on the ellipse, set the compass to A2 and with F' as a center, strike an arc; then set the compass to B2 and with F as a center, strike an intersecting arc. Proceed in this manner to plot 5 points on the ellipse between C and B. To plot 5 points between C and A, proceed in the same manner, but reverse the foci in drawing the arcs. To plot 5 points between B and D, use the foci as you used them in plotting the points between C and B. To plot 5 points between A and D, use the foci as you used them in plotting the points between C and A. After you have learned the method, you can plot the points in the right-hand half of the ellipse in a single operation, and the points in the left-hand half in another single operation.

Ellipse by Concentric Circle Method

Figure 4-64 illustrates the concentric circle method of drawing an ellipse. With the point of intersection between the axes as a center, draw two concentric circles (concentric circles are circles having the same center), one with diameter equal to the major axis and the other with diameter equal to the minor axis, as shown in 4-64 (A). Draw a number of diameters as shown in 4-64(B). From the point of intersection of each diameter with the larger circle, draw a vertical line; and from the point of intersection of each diameter with the smaller circle, draw an intersecting horizontal line, as shown in 4-64(C). The points of intersection between these lines lie along the ellipse, as shown in 4-64(D).

Figure 4-63.—Ellipse by foci method.

Figure 4-64.—Ellipse by concentric circle method.

Figure 4-65.—Ellipse with given conjugate diameters.

Ellipse, Given Conjugate Diameters

Each of the ellipses discussed in the previous sections has been given in terms of a horizontal and a vertical axis, one of which is perpendicular to the other. An ellipse may also be given in terms of conjugate diameters. Two diameters of an ellipse are conjugate when each is parallel to the tangents at the ends of the other. One of a given pair of given conjugate diameters is, as a rule, not perpendicular to the other.

Figure 4-65 shows the parallelogram method of drawing an ellipse with given conjugate diameters AB and CD. Draw the circumscribing parallelogram EFGH. Divide EA and AO into the same number of equal intervals. Draw lines

Figure 4-66.—Parabola.

from D passing through the intervals of AO, the lines from C to the intervals of EA. The points of intersection of these lines lie on the ellipse.

Parabola

Figure 4-66 illustrates a method of drawing a parabola. The problem is to draw a parabola which starts at A, ends at B, and has CO as an axis. Draw AD, DE, and BE, creating the rectangle ADEB. Divide AD and BE into a number of equal intervals, and divide AB into twice that number of equal intervals. Draw lines from C to the intervals along AD and BE, and erect perpendiculars from the intervals along AB to intersect these lines. The points of intersection lie along the parabola.

Figure 4-67.—Ellipse by general method for drawing conic sections.

This method is a general method which can be used to draw any conic section. Figure 4-67 illustrates the use of the method in drawing an ellipse with major axis AB and minor axis CD. The use of the method in drawing an ellipse with given conjugate diameters is illustrated in figure 4-65.

Hyperbola

Figure 4-68 illustrates the use of the general method for drawing a hyperbola. The problem here is to draw a hyperbola which starts at A, ends at B, and has CO as a vertical axis (AB is the transverse axis). Draw AD, DE, and BE, creating the rectangle ADEB. Divide AD and BE into a number of equal intervals,

Figure 4-68.—Hyperbola.

Figure 4-69.—Spiral of Archimedes.

and divide AB into twice that number of equal intervals. Extend OC to C'. The amount you extend it depends upon how sharp you want the curve of the hyperbola to be. The longer you make C'O, the flatter the curve will be.

Draw lines from C to the intervals along AD and BE, and lines from C' to the intervals along AB. Points of intersection between these lines lie on the hyperbola, as illustrated.

Spiral of Archimedes

A spiral of archimedes is a curve which follows the path which would be traced by a point moving around and away from a fixed point (called the pole) in such a manner that the distance of the point from the pole increases uniformly with the angle.

The method of drawing a spiral of Archimedes is based on this definition. In figure 4-69, the problem is to draw a spiral of Archimedes beginning at the pole designated by the letter O. Draw a series of radii from O, with equal angles between the radii (an angle of 30° is suitable). Select an appropriate interval on a scale, pick a starting radius, and lay off the interval from the pole on the radius. On the next radius, lay off twice the interval; on the next, three times the interval, and so on. This will produce the series of numbered points shown in the figure. Draw a line through the points with a french curve.

CONSTRUCTING FAIRED CURVES

In general, a curve is considered smooth or faired if a draftsman using a normally straight spline with ducks can make it lie on all points of the curve without forcing it. If any of the ducks, except one at an end, is lifted, the spline should not spring away from its position. That is, the curve should be perfectly smooth with no slight reverse curves in it.

Figure 4-70 illustrates a method of constructing a faired curve geometrically when only three points on the curve are known:

1. Locate the points for clearance, shown as A, O, and B in figure 4-70.
2. Draw a base line through point A, a line through point A which is perpendicular to the base line, and a line through point B which is parallel to the base line, thus locating point C. (See fig. 4-70A.)
3. Draw lines AD and BE through point O. (See fig. 4-70A.)
4. Draw AF so that it crosses BE at any point above O, as shown in figure 4-70B.
5. Through the intersection of AF and BE, draw line CG. (See fig. 4-70B).
6. Draw line BH through the intersection of AD and CG. The intersection of this line BH with AF is a point on the curve, as shown in figure 4-70B.
7. Continue this procedure, as shown in figures 4-70C and 4-70D, until as many points on the curve as are desired have been located.

DIMENSIONING

Since an engineering drawing is made to be used in producing or constructing something, the dimensions on the drawing must be drawn and lettered accurately. In drawing extension and dimension lines and in lettering dimensions, keep in mind the man who has to read the drawing and make something from it. All the dimensions a workman will need should be included on the drawing. It should never be necessary for him to stop his work to make mathematical computations that should have been given to him. In MIL-STD-8C, Dimensioning and Tolerancing, the general rules which are followed throughout the Defense Department are discussed at length.

Figure 4-70.—Layout for a faired curve through a set of points.

Placing Dimensions

Place as many dimensions on the principal view as you can without crowding them. Dimensions of surfaces which show on the outlines of two views should be placed between these views. On views other than the principal view, show dimensions only for those features which do not have their true shape on the principal view. Dimensions should be placed outside the view whenever possible. If you can avoid it, do not dimension to hidden lines.

Two systems are used in dimensioning. The rectangular system is shown in figure 4-71, and the angular system in figure 4-72. In the rectangular system, horizontal or vertical dimension lines are drawn parallel to the distance to be dimensioned, with any necessary extension lines drawn perpendicular to that distance. In the angular system, the position of a point, line, or surface is shown by means of angles and linear dimensions at an angle other than 90°.

When a number of distances that are side by side on a drawing are to be dimensioned, place the dimension lines and figures in line where space permits. (See fig. 4-73a.)

Dimension lines should not cross other lines. The dimensions should be grouped with

Figure 4-71.—Rectangular dimensioning.

Figure 4-72.—Angular dimensioning.

Figure 4-73.—a. Placing dimensions.
b. Staggering dimensions.

Figure 4-74.—Methods of dimensioning a small space.

Figure 4-75.—Leader used in dimensioning small circles.

the smallest dimension closest to the outline of the view and the larger dimensions stepped out at equal distances. (See fig. 4-73.) When it is impossible to avoid drawing leader lines across a dimension line, break the leaders. Avoid crowding dimension lines. The lines should be spaced at least 3/8-inch from the view and at least 3/8-inch apart when the dimensions are stepped out from the view.

Where the space to be dimensioned is small:

1. The dimension line with arrows may be drawn inside the space between extension lines and a line drawn leading to the figure outside. (See fig. 4-74a.)

2. The figure may be placed in the space between extension lines, aligned with arrows pointed toward it from outside the lines, as shown in figure 4-74b.

3. The arrows may be trained on the space, which is left blank, and the dimension lettered at the end of one of the arrows. (See fig. 4-74c.)

In the dimensioning of small circles, leaders are used as in figure 4-75. The abbreviation DIA should follow the diameter dimension unless it is clearly a dimension figure as shown by a dimension line drawn inside the circle at an angle to represent the diameter or by a note such as drill.

In the dimensioning of larger circles, the rectangular system may be used; or a dimension line may be drawn as a slanted diameter to the circle and an extension line exactly like a leader, but without an arrow, drawn to the dimension numeral, as in figure 4-72.

In the dimensioning of arcs of circles, a leader defining the radius is used, with its

Figure 4-76.—Dimensioning arcs.

Figure 4-77.—Dimensioning angles.

arrowhead terminating in contact with the arc. (See fig. 4-76a.) On large arcs, where the center of the circle would fall off the drawing, a long break, or zigzag, is drawn in the leader line, and the dimension is placed between the zigzag and the arrowhead. (See fig. 4-76b.) The letter R should always follow the dimensions of a radius.

In the dimensioning of angles, the dimension lines are drawn as arcs. (See fig. 4-72.) The position of the dimension figure will vary according to the size of the angle, as shown in figure 4-77.

Dimension Numerals and Letters

It is important to leave enough space between letters and figures in order to prevent their becoming blurred when your drawing is reproduced to a smaller scale. Decimal points should be slightly heavier than the lines in the lettering and should be spaced carefully.

All letters and numerals should be so placed on a drawing that they are easy to read without turning the drawing. On one drawing they may all be placed in a horizontal position. On another, the vertical and angular dimensions may be placed in such a manner that they may be read from the right-hand side of the drawing.

Tolerance figures on mechanical drawings represent the amount a part can be allowed to vary within a dimension when the part is made. When no tolerance is given with the individual dimensions, there should be a general tolerance note on the drawing. When there is no general note, tolerance figures may be placed either just to the right of the dimension or directly beneath the dimension. The numerals are placed in a break in the line or, if the tolerance figure is below the dimension, the line may pass between them.

There are several ways of indicating tolerance. With the UNILATERAL METHOD, the minimum or the maximum measurement is used as the dimension figure, and the difference allowable is given as a plus or minus tolerance figure. (See fig. 4-78.) In the BILATERAL METHOD, the dimension figure indicates the plus or minus variation acceptable. (See fig. 4-78b.) In the LIMIT DIMENSIONING METHOD, the maximum and minimum measurements are both stated. (See fig. 4-78c.)

THEORY OF PROJECTION

CENTRAL PROJECTION

Projection is done, in theory by extending lines of sight (called projectors) from the eye of the observer through lines and points on the object to the plane of projection. If this procedure were literally followed, the result would always be the type of projection illustrated in figure 4-79. This type is called central projection, since the lines of sight or projectors converge at a single central point—the eye of the observer.

You can see that the projected view of the object varies considerably in size, according to the relative positions of the object and the plane of projection. It would also vary with the distance between these two, and with the distance between the observer and the object and between the observer and the plane of projection. For these and other reasons, central projection is seldom used for the projection of technical drawings.

Figure 4-78.—Methods of indicating tolerance.

Figure 4-79.—Central projection.

PARALLEL PROJECTION

If the observer were located an infinite distance away from the object and its plane of projection, the projectors, instead of converging together to a point, would be parallel to each other. For reasons of convenience, this is presumed to be the case for most technical drawing. Figure 4-80 illustrates parallel projection. You can see that, if the projectors are perpendicular to the plane of projection (as they are in fig. 4-80), a parallel projection of an object has the same dimensions as the object, regardless of the relative positions of the object and the plane of projection, and regardless of the distance away of the observer.

ORTHOGRAPHIC AND OBLIQUE PROJECTION

A parallel projection in which the projectors are perpendicular to the plane of projection (as they are in fig. 4-80) is called an orthographic projection. One in which the projectors

Figure 12-16.—High powered coupled cavity TWT.

Coupling and Attenuation

Input and output coupling methods, and the means of attenuating signals in the TWT circuits, are generally of the same types discussed in chapter 9 of AT 3 & 2, NavPers 10317-C in connection with waveguides and cavity resonators. A review of these coupling and attenuating methods may be of some help at this time.

APPLICATIONS

The traveling wave tube has proved itself a very versatile device. Among the applications to which it has been put are:

1. Amplifiers—tunable and fixed frequency; input and IF; amplitude, phase, pulse, and frequency modulated; and phase and frequency shifters.
2. Limiters and automatic gain control devices.
3. Microwave frequency generators—fixed frequency, narrowband or wideband, or tunable; frequency multipliers.

Some of these applications will be discussed in the following paragraphs, along with details of construction and variations of the tubes and circuit functions.

Amplifier

The most noteworthy characteristic of the traveling wave tube is its ability to amplify microwave signals through a wide band of frequencies. This amplification is obtained through the use of the interaction circuit. This circuit is basically a transmission line, and usually does not contain a resonant circuit of any kind. By avoiding the use of resonant circuits, the TWT is not subject to the normal gain-bandwidth formula (which states that as the bandwidth is increased, the gain decreases, and vice versa). To date, the TWT is the only amplifying device used at microwave frequencies that does not use resonant cavities for amplification. The gain-times-bandwidth product of the TWT may be in the order of 10^{13}. TWT's have been constructed to operate in frequency bands from 100 mc to 50,000 mc.

In the helix type slow wave circuit (fig. 12-17), this gain takes place as described in the following paragraphs.

The electron beam is injected into the interaction region at the electron gun end of the slow wave structure. The velocity of the beam

Figure 4-80.—Parallel projection.

Figure 4-81.—Oblique and orthog aphic projections of the same object.

are oblique (other than perpendicular) to the plane of projection is called an oblique projection.

Figure 4-81 shows the same object by both orthographic and oblique projection. The block is placed so that its front surface (the surface toward the plane of projection) is parallel to the plane of projection. You can see that the orthographic projection shows only this surface of the block. The oblique projection, on the other hand, shows the front surface and also the top surface. The orthographic projection shows only two dimensions of the block, the length and the width. The oblique projection shows three, the length, the width, and the thickness. Oblique projection, then, is one method by which an object can be shown, in a single view, in all three dimensions.

SINGLE-PLANE PROJECTION

A projection which shows an object in all three dimensions is called a single-plane projection, because only a single plane of projection is required to show all three dimensions. A single-plane projection may be either an oblique or an axonometric projection.

OBLIQUE SINGLE-PLANE PROJECTION

The two most commonly used types of oblique single-plane projection are the cavalier projection and the cabinet projection.

Cavalier Projection

Cavalier projection is a form of oblique projection in which the projectors are presumed to make a 45-degree vertical and a 45-degree horizontal angle with the plane of projection. Assume that in figure 4-82 the line XX' represents a side-edge view of the plane of projection, and that the square ABCD represents a side of a cube, placed with its front face parallel to, and its top face perpendicular to, the plane of projection. You can see that the projected lengths of AB and AC are the same as the actual lengths.

Now assume that the line XX' in figure 4-82 represents a top-edge view of the plane of projection, and that the square ABCD represents the top of the cube. You can see again that the projected lengths of AB and AC are the same as the actual lengths of AB and AC.

In a cavalier projection, then, any line parallel to or perpendicular to the plane of projection is projected in its true length. Figure 4-83 shows a cavalier projection of the cube shown in figure 4-82. You start by drawing the axis, which consists of the front axes OA and OB and the receding axis OC. The front axes are always perpendicular to each other; the receding axis may be drawn from

O at any convenient angle. All three are equal in length, the length being the length of an edge of the original cube (which may be scaled down or up, of course, if the drawing is made other than full scale). After you draw the axis, complete the projection by drawing the required parallel lines. All the edges shown in the projection are, like the edges on the original cube, equal in length.

Cabinet Projection

The first thing you notice about the cube shown in figure 4-83 is the fact that it doesn't

Figure 4-83.—Cavalier projection of a cube.

Figure 4-82.—Angle of projectors in a cavalier projection.

look like a cube, because the depth dimension appears to be longer than the height and width dimensions. The reason for this is the fact that a cavalier projection corrects a human optical illusion—the one which causes an object to appear to become smaller as its distance from the eye increases. This illusion in turn causes receding parallel lines to appear to the eye to be shorter than they really are, and also

Figure 4-84.—Cabinet projection of a cube.

to be converging toward a point in the distance. But receding parallel lines on a cavalier projection appear in their true lengths, and they remain constantly parallel. Also, the far edges of the cube shown in figure 4-83 are equal in length to the near edges.

The apparent distortion in figure 4-83 is only apparent, but the eye is so accustomed to its illusions that it is sometimes desirable in pictorial drawings, to reduce the appearance of distortion. This can be done in an oblique projection by reducing the length of the receding axis (OC in fig. 4-83). This axis can be reduced by any desired amount, but it is customary to reduce it by one-half. When the receding axis is reduced by one-half, the projection is called a cabinet projection. Figure 4-84 shows a cabinet projection of a cube. The length of the

Figure 4-85.—Isometric projection of a cube.

receding axis OC has been reduced by one-half. As you can see, the eye is much more satisfied with this representation of a cube.

PROJECTION AXONOMETRIC SINGLE-PLANE

AXONOMETRIC single-plane projection is another way of showing an object in all three dimensions in a single view. Axonometric projection is orthographic projection—meaning that in axonometric projection the projectors are perpendicular to the plane of projection. It is the object itself, rather than the projectors, that is inclined to the plane of projection.

Figure 4-86.—Isometric axis.

Isometric Projection

Figure 4-85 shows a cube projected by isometric projection, the most frequently used type of axonometric projection. The cube is inclined so that all of its surfaces make the same angle (35° 16′) with the plane of projection. As a result of this inclination, the length of each of the edges shown in the projection is somewhat shorter than the actual length of the edge on the object itself. This reduction is called foreshortening. The degree of reduction amounts to the ratio of 1 to the cosine of 35° 16′, or 1/0.8165. This means that if an edge on the cube is 1 in. long, the projected edge will be 0.8165 in. long. As all of the surfaces make the same angle with the plane of projection, the edges all foreshorten in the same ratio. Therefore, one scale can be used for the entire layout; hence the term "isometric," which literally means "one-scale."

Figure 4-87.—Dimetric projection of a cube, showing a practical dimetric axis.

Figure 4-86 shows the isometric projection shown in figure 4-82 as it would look to an observer whose line of sight was perpendicular to the plane of projection. Note that the figure has a central axis, formed by the lines OA, OB, and OC. The existence of this axis is the origin of the term "axonometric projection." In an isometric projection, each line in the axis forms a 120-degree angle with the adjacent line, as shown. A quick way to draw the axis is to draw the perpendicular OC, then use a T-square and 30-60 degree triangle to draw OA and OB at 30° to the horizontal. Since the projections of parallel lines are parallel, the projections of the other edges of the cube will be respectively parallel to these axes.

Isometric Drawing

Assume that the projection shown in figure 4-86 is a projection of a cube measuring 1" x 1" x 1". If you drew this cube to full scale, each line in the isometric projection would be 0.8165 in. long.

Now, if you made each line in the drawing 1 in. long instead of 0.8165 in. long, the drawn figure would be slightly larger, but there would be no perceptible difference in its appearance otherwise. The proportions of the figure, with relation to each other, would be the same. Consequently, in practical draftsmanship it is often the case that an isometric drawing, rather than an isometric projection, is made. In full-scale isometric projection, dimensions are scaled down to the scale of 0.8165 (which comes to about 4/5 scale, or about 9.6" = 1 ft), to allow for foreshortening. In an isometric drawing foreshortening is ignored, and the dimensions on the drawing are the same as those on the object—except, of course, that for a drawing other than full scale they are scaled down or up to the scale selected for the drawing.

Dimetric Projection

The cube shown in figures 4-85 and 4-86 is inclined so that all of its surfaces make the same angle with the plane of projection. The cube has three pairs of opposing, parallel surfaces. In an isometric projection, all three pairs make the same angle with the plane of projection.

In a diametric projection the cube is inclined so that only two pairs of surfaces make the same angle with the plane of projection, while the third pair makes a different angle. Figure 4-87 shows a dimetric projection of a cube. The pairs of surfaces which form the sides make the same angle with the plane of projection; the pair which forms the top and bottom make a different angle. Consequently, the foreshortening of the dimensions of the side surfaces is not the same as the foreshortening of the dimensions of the top and bottom surfaces. You must use two different scales to scale down for foreshortening; this is the origin of the term "dimetric," which literally means "two-scale."

The axis of an isometric projection of a cube always consists of three lines at a 120-degree angle to each other, as illustrated in figure 4-86. The similar axis on a dimetric projection of a cube is variable, according to the angle of inclination of one pair of surfaces of the cube to the plane of projection. However, there are three axes which are suitable for almost any practical dimetric projection or drawing. One is the axis shown in figure 4-87. You can draw this one by drawing the perpendicular OC and using a protractor to draw OA and OB from O at 13° 38' to the horizontal. If you use this axis, the scale of foreshortening is 3/4 for OA and OB to 1 for OC. You can ignore the foreshortening of OC—that is, you can make OC the length of the original (to scale, of course, if the drawing is not being done full-scale). This means that you are making a dimetric drawing, rather than a dimetric projection.

Figure 4-88.—Another practical dimetric axis.

Another practical dimetric axis is shown in figure 4-88. You can draw this one by drawing the perpendicular OC and then drawing OA and OB from O at 36° 50' to the horizontal. If you use this axis, the scale for foreshortening is 3/4 for OC to 1 for OA and OB.

In the dimetric projection shown in figure 4-89, it is the top and bottom pair of surfaces and one pair of side surfaces that make the same angle with the plane of projection; the other pair of side surfaces make a different angle. A practical dimetric axis for a cube in this position is shown in the figure. You can draw this one by drawing the perpendicular OC, then drawing OA from 0 at 7° 10' to the horizontal and OB from 0 at 41° 25' to the horizontal. If you use this axis, the scale for foreshortening is 1/2 for OB to 1 for OA and OC.

Trimetric Projection

In a trimetric projection the cube is inclined so that all three pairs of surfaces make different angles with the plane of projection. Figure 4-90 shows a trimetric projection of a cube. The foreshortening is different for each of the three pairs of surfaces; therefore, three

Figure 4-89.—Practical axis for cube placed in different dimetric position.

Figure 4-90.—Trimetric projection of a cube.

Figure 4-91.—Multiview planes of projection.

different scales would be required to scale down for foreshortening. This is the origin of the term "trimetric," which literally means "three-scale."

Trimetric projection is much more difficult than isometric or dimetric projection, and it has few, if any, advantages over either of these other methods. Trimetric projection is therefore seldom used in actual practice.

MULTIVIEW PROJECTION

Oblique and axonometric projections are known as single-plane (or single-view) projections, because only a single view of the object is presented. Most technical drawings, however, are made by orthographic multi-plane, more commonly called multiview, projection. In this type of projection the object as it appears on all sides, and in top and bottom views, can be shown by the use of more than one plane of projection.

Figure 4-91 shows the three principal multiview planes of projection, known as the vertical, horizontal, and profile planes. As you can see, they intersect each other at right angles. The angles between the horizontal and the vertical planes are called the first, second, third, and fourth angles, as indicated in the figure.

FIRST-ANGLE PROJECTION

You could place the object to be projected in any one of the four angles. For technical reasons, second-angle and fourth-angle projections are not used. First-angle projection is used in most European countries, but not used much in the United States. Figure 4-92 shows a cube placed for first-angle projection. The cube is supposed to be fronting toward the vertical plane of projection. As you can see, you get a front view on the vertical plane, a left-side view on the profile plane, and a top view on the horizontal plane.

Figure 4-92.—First-angle projection of a cube.

Figure 4-93.—First-angle projection brought into a single plane.

Now, to put these views on a sheet of drawing paper, you must get them all into the same plane. You presume that the vertical plane of projection is already in the plane of the paper. To get the other two into the same plane, you rotate the profile plane counterclockwise and the horizontal plane clockwise. The projection now appears as shown in figure 4-93.

This first-angle projection arrangement of views is considered satisfactory in most European drafting practice. In the U.S. it is considered illogical, because the top view is below the front view; because the right side of the object, as shown in the front view, is toward the left-side view of the object; and because the bottom of the object, as shown in the front view, is toward the top view of the object. For these and other reasons, first-angle projection is not used much in the U.S.

THIRD-ANGLE PROJECTION

Figure 4-94 shows a third-angle projection of a cube. As you can see, you get a front view on the vertical plane, a top view on the horizontal plane, and a right side view on the profile plane.

Again you assume that the vertical plane is already in the plane of your drawing paper. To get the other two into the same plane, you rotate them both clockwise. The projection now appears as shown in figure 4-95. The top view is above the front view; the right side of the cube, as shown in the front view, is toward the right side view; and the top, as shown in the front view, is toward the top view.

Figure 4-94.—Third-angle projection of a cube.

Figure 4-95.—Third-angle projection brought into a single plane.

Figure 4-96.—Method of making a third-angle projection.

Figure 4-97.—Alternate methods of extending top view projectors.

Figure 4-96 illustrates the basic principles of the method by which you would actually make the projection shown in figure 4-95. Draw a horizontal line AB and a vertical line CD, intersecting at O. AB represents the joint between the horizontal and the vertical plane; CD represents the joint between these two and the profile plane. Draw the front view, and project it upward with vertical projectors to draw the top view. Project the top view to CD with horizontal projectors. With O as a center, use a compass to extend these projectors to AB. Draw the right side view by extending the projectors from AB vertically downward, and by projecting the right side of the front view horizontally to the right.

Many draftsmen prefer to extend the top view projectors to the right side view by one of the methods illustrated in figure 4-97. In figure 4-97(A) the projectors are extended from CD to AB by lines drawn at 45° to AB. In figure 4-97(B) the line OE is drawn at 45° to AB, and the top view projectors are extended horizontally to OE and then vertically downward.

ARRANGEMENT OF VIEWS

The projection shown in figure 4-96 and 4-97 is a three-view multiview projection, showing 3 surfaces of the cube. A cube has 6 surfaces, however, and all 6 can be shown in a multiview projection. Technically speaking, there are still only 3 planes of projection, but for (for example) a back view, the vertical plane is presumed to be moved to a position between the observer and the back surface of the block. Actually, this amounts to the assumption that there are 6, rather than only 3, planes of projection: the front and back planes (both of which are vertical), the top and bottom planes (both of which are horizontal), and the right and left side planes (which are perpendicular to the other two pairs of planes).

If only the front, top, and right side views are shown, the standard American arrangement of views is the third-angle arrangement shown in figure 4-96 and 4-97. If a left side, bottom and back view are shown as well, the American standard arrangement is that illustrated in figure 4-98.

Figure 4-98.–American standard arrangement of views in 6-view third-angle multiview projection.

In architectural drawings, a top view is called a plan, and a front, back or side view an elevation. A top view of a house, for instance, is a plan; a floor plan shows a top view of the house as it would look if it were cut away at the level of that particular floor. A front view of a house is a front elevation, a back view is a rear elevation, and a right side view is a right side elevation. The terms plan and elevation apply principally to architectural drawings, but they are often applied to drawings of other than architectural objects.

VIEW ANALYSIS

You must be able to analyze a multiview projection—meaning, to determine what each line in a particular view represents. In this connection, it is helpful to remember that in a third-angle projection the plane of projection is always presumed to be between the object and the observer, regardless of which view you are considering. This means that, in a third-angle projection, each view of a surface of an object is a view of that surface as it would appear to an observer looking directly at it.

Figure 4-99 shows a 6-view multiview third-angle projection of the block shown in cabinet projection in the upper left corner of the figure. You don't have any trouble analyzing the front view; you know that the top is up, the bottom is down, the left side is to the left, and the right side is to the right.

In the top and bottom views it's easy to see that the right-hand vertical line represents the right side and the left-hand vertical line the left side. But you might have to think a minute to realize that the upper horizontal line in the top view represents the back face of the block, while the upper horizontal line in the bottom view represents the front face of the block. Note, also, that there is a line which appears as a visible line in the top view and as a hidden line in the bottom view.

In the right side and left side views, you can readily see that the upper horizontal line represents the top of the block and the lower horizontal line the bottom. But you may have to think a minute to realize that the left-hand vertical line in the right-side view represents the front face of the block, while the left-hand vertical line in the left side view represents the back face. Again there is a line which appears as a visible line in the right side view and as a hidden line in the left side view.

In the back view the block is shown reversed, so that the cut-away part which appears

Figure 4-99.—Multiview view analysis.

to the right in the front view appears to the left in the back view. Similarly, the right-hand vertical line in the front view represents the right side of the block, while the corresponding line in the back view represents the left side.

As a general observation, it is helpful in view analysis to note that in the top, bottom, and side views the line which represents the front face of the block faces toward the front view of the block. Similarly, in the back view the line which represents the left side faces toward the left side view of the block. All this applies to third-angle projection only.

CHOICE OF VIEWS

A multiview projection should contain only as many views as are required to describe the object fully. If you refer back to figure 4-99, you can see at once that the back view does not convey any information which is not available in the front view; the back view is therefore superfluous and should be omitted. The same applies to the bottom view, which conveys no information not available in the top view. Likewise, the left side view conveys no information not available in the right side view.

Figure 4-100.—Two-view multiview projections.

Figure 12-17. —Helix type TWT amplifier.

is determined by the d-c potential between the slow wave structure and the cathode of the gun. The beam is focused, by the focusing device, into a cylindrical beam whose diameter is approximately the same as the diameter of the inside of the slow wave structure.

An electromagnetic wave is injected into the same region at the gun end, and travels along the circumference of the slow wave structure at nearly the velocity of light. Due to the physical construction of the slow wave structure, the electron beam (in its direct path) and the electromagnetic wave (in its longer path) travel together along the slow wave structure at approximately the same forward velocity. The beam accelerating potential is adjusted so that the beam velocity is slightly greater than the wave velocity.

As in the magnetron, interaction of the RF electric field upon the electron beam will result in the acceleration of electrons in certain regions, and deceleration of other electrons in other regions. As the beam progresses along the slow wave structure, the decelerating action becomes predominant, and d-c energy from the electron beam is transferred to the RF electric field, resulting in amplification of the RF input signal.

Saturation may occur in a TWT, as in other types of electron tubes. In the TWT, this condition results from the RF field becoming excessive, due to either too large an input or too much gain. This represents the maximum power output of the tube for a given value of beam current. An increase in beam current will permit a further increase in output power, but the increases are not linear functions. For low input levels the gain is nearly constant, while the gain becomes less at higher input levels. Increasing the input beyond the saturation point results in decreased power output.

Maximum gain that can be realized from a TWT circuit is dependent on, and limited by, the following conditions:

1. The beam current value at which the tube will oscillate.

You have the choice of omitting either the top or bottom view and either the right side or left side view. One general rule in this instance is that a top view is preferable to a bottom view and a right side view to a left side view; another rule is that a view with a visible line is preferable to a view with the same line shown as a hidden line. Both rules apply here to eliminate the bottom and the left side views. All you need here is a three-view projection, showing the top, front, and right side views.

It is often the case that a two-view projection is all that is required. Figure 4-100(A) shows a cabinet projection of a board. It is obvious that a top view of this object tells you everything you need to know except the thickness; a right side view tells you everything you need to know except the length; and a front view tells you everything you need to know except the width. All you need to do, then is to select a particular view and couple it with another view which gives you the dimension which is missing in the first view. There are three possible two-dimension projections of the board, illustrated in (A), (B), and (C). In the selection of one of these three, everything else being equal, the balance of the drawing would be the deciding factor. Either (A) or (B) appears better balanced than (C), and between (A) and (B), (A) would look better on a long oblong sheet of paper and (B) better on a shorter oblong sheet.

The object shown in figure 4-100 has a definitely designated top and front; it follows that the right and left sides are also definitely designated. This is the case with many objects; you have no choice, for example, with regard to the top, bottom, front, and back of a house. Many objects, however, have no definite top or bottom, or front or back—many types of machine parts, for example. With an object of this kind, you can select a surface and call it the front, select another and call it the top, according to convenience. However, it is a general rule that an object should be shown in the position it customarily occupies. Suppose that the board shown in figure 4-100 is a floor board. Then the top would be as indicated in the figure. If it were a wall board, however, one of the long narrow edges would be the top, and one of the wide faces would be the front.

SPACING VIEWS

Views should be spaced on the paper to give the appearance of a balanced drawing. Figure 4-101 shows two-view drawings properly spaced on size A (8 1/2" x 11"), size C (17" x 22"), or size E (34" x 44") drawing paper. Marginal distances should be equal as indicated; distance B should be equal to, or slightly less than, distance A.

An easy way to determine the length of distance A in the upper drawing shown in figure 4-101 is as follows. Set a compass to the length plus the thickness of the object and

Figure 4-101.—Proper spacing of views on a 2-view projection.

lay off this distance from one end of one of the horizontal margins of the drawing. One-third of the length of the remaining segment of the margin is the length of distance A. To determine the length of distance C in the same drawing, set a compass to the width of the object and lay off this distance from one end of one of the vertical margins of the drawing. One-half of the length of the remaining segment of the margin is the length of distance C.

9910 free

Figure 4-102.—Proper spacing of views on a 3-view projection.

Figure 4-103.—Improved spacing for 3-view projection of object shown in figure 4-102.

Proper spacing of a three-view drawing is shown in figure 4-102. As you can see, the principle is the same as that applied in spacing a two-view drawing. Distances are again equal as indicated, with distance B equal to, or slightly less than, distance A, and distance D equal to, or slightly less than distance C.

While the spacing of views in figure 4-102 is technically correct, the drawing has an unbalanced appearance, because of the large area of empty space in the upper right corner, and because the right side view crowds the title block. If the drawing will contain a sizeable bill of materials in the upper right corner, this spacing will be satisfactory. If not, it should be improved, if possible.

If the object is one which allows an arbitrary choice with regard to the designation of surfaces as top, front, and so on, the spacing can be improved by changing the designation shown in figure 4-102, and projecting the object as shown in figure 4-103. What appears as the top in figure 4-102 you can now call the front; it follows that what appears as the front in figure 4-102 appears as the bottom in figure 4-103. Again the right side view appears, but it now appears in the upper rather than the lower right corner, and vertically rather than horizontally.

Spacing views in a drawing of a circular object is like spacing letters—you try to equalize the areas of the spaces around and between the views. Figure 4-104 shows properly spaced two-view drawings of a perforated disk. For the views which are horizontally in line, you locate the horizontal center line midway between the horizontal margins; for the views which are vertically in line, you locate it midway between the vertical margins. The other spacing is as indicated. To determine the lengths of distances A and 2/3 A in the upper drawing, set a compass to the diameter plus the thickness of the disk, and lay off this distance from one end of one of the horizontal margins. Then divide the remaining segment of the margin into three intervals, two of them being equal, and the third one and one-half times as long as each of the others.

Figure 4-104.—Spacing of views of a circular object.

HIDDEN LINE TECHNIQUES

To prevent confusion in the interpretation of hidden lines, you must apply certain standard techniques in drawing these lines. A hidden line which is supposed to join a visible or another hidden line must actually contact the line, as shown in the upper views of figure 4-105; the incorrect procedure is shown in the lower views.

Figure 4-106 shows an intersection between a hidden line and a visible line. Obviously, on the object itself the hidden line must be below the visible line. You indicate this fact by drawing the hidden line as shown in the upper view

Figure 4-105.—Correct and incorrect procedures for drawing adjoining hidden lines.

of figure 4-106. If you drew it as indicated in the lower view, the hidden line would appear to be above, rather than beneath, the visible line.

Figure 4-107 shows an intersection between two hidden lines, one of which is beneath the other on the object itself. You indicate this fact by drawing the lines as indicated in the upper view of figure 4-107. If you drew them as indicated in the lower view, the wrong line would appear to be uppermost.

NUMBERING CORNER POINTS

A point which constitutes a corner on an object may be numbered, to facilitate interpretation of drawings of the object. A corner point may be hidden or visible in a particular view of the object. See figure 4-108, for example. In the upper left corner of this figure there is a cavalier projection of a block. You can see that point 2 on this block would be visible in a top, back, or right side view of the block, but hidden in a bottom, front, or left side view.

The rule for corner-point numbering is that for a point which appears as a hidden point the number is placed inside the outline, while for a point which appears as a visible point, it is placed outside the outline. You can see how the rule has been followed in the 6-view projection shown in figure 4-108.

Figure 4-106.—Correct and incorrect procedures for drawing hidden line which intersects visible line.

Figure 4-107.—Correct and incorrect procedures for drawing intersecting hidden lines which are on different levels.

NORMAL AND OBLIQUE LINES

A NORMAL line in a multiview projection is one which is parallel to two of the planes of projection and perpendicular to the third. A line which is parallel to a plane of projection will appear on that plane in its true length (which may, of course, be scaled up or down for a drawing which is other than full-scale). A line which is perpendicular to a plane of projection will appear on that plane as a point.

A line which is perpendicular to one plane of projection must be parallel to the other two. But a line which is parallel to one plane of projection may be oblique to one or both of the others. Such a line will appear in its true length in a view on the plane to which it is parallel, but will appear foreshortened in a view on a plane to which it is oblique. A line may, of course, be oblique to all three planes of projection, in which case it will appear foreshortened in all regular views of the object.

Figure 4-108.—Procedure for numbering hidden and visible corner points.

Consider figure 4-109, for example. In the upper left corner there is a cavalier projection of a block. This block is placed with its front parallel to the vertical plane, bottom parallel to the horizontal plane, and right side parallel to the profile plane. Then the line AB is parallel to the vertical plane, but oblique to both the horizontal and the profile planes. In the multiview projections shown in the same figure, you can see that it is only in the front and the back views (which are views on the vertical plane, to which AB is parallel) that AB appears in its true length. In all the other views (which are views on planes to which AB is oblique), AB is foreshortened. But you will note that you do not need to concern yourself with the amount of this foreshortening, since it works itself out as you project the various views.

Figure 4-109.—Foreshortening of a line in a multiview projection.

Figure 4-110.—A line oblique to all planes of projection is foreshortened in all views.

In the upper left of figure 4-110 there is a cavalier projection of a triangular block. The right side is presumed to be parallel to the profile plane of projection, the bottom to the horizontal plane. The line AB is oblique to all three planes.

The true length of AB is shown in the small triangle to the left of the cavalier projection; it is the length of the hypotenuse of a triangle with altitude equal to the vertical height of the block and base equal to the length of AB as it appears in the top view multiview projection. You can see that AB is foreshortened in all of the multiview views. Once again, however, the amount of foreshortening works itself out as you project the views.

CIRCLES

In a multiview projection, a circle on a surface which is parallel to the plane of projection will project as a circle. One on a surface which is oblique to the plane of projection will project as an ellipse, as shown in figure 4-111. The upper view of this figure is a top view of a wedge-shaped block, the block having a circular hole bored through it perpendicular to the inclined face. The outline of this hole on the front face of the block projects as an ellipse in the front view of the block. You get the minor axis of the ellipse by projecting downward, as shown. The length of the major axis is equal to the length of the diameter of the hole.

Figure 4-111.—A circle on a surface oblique to the plane of projection projects as an ellipse.

There is another ellipse in the front view: the partly hidden and partly visible outline of the hole as it emerges through the back of the block. This outline, too, is elliptical, because the hole, though it is circular, is bored obliquely to the back surface of the block. Since the vertical plane is parallel to the back surface of the object, this outline gives the true shape of the hole as it emerges from the back of the block. You get the major axis for this ellipse by projecting downward, as shown. The length of the minor axis is the same as the length of the diameter of the circular hole.

To draw these ellipses you may use any of the methods of drawing an accurate ellipse explained earlier. However, in a case of this kind an approximate ellipse, which can be quickly and easily drawn with a compass, is usually satisfactory. A method of drawing an approximate ellipse is illustrated in figure 4-112. The major axis is AB, the minor axis CD. Set a compass to the length of AO, and with O as a center, strike an arc intersecting OC (extended) at E. Draw the straight line AC, set the compass to the length of EC, and with C as a center, strike an arc intersecting AC at F. Draw a perpendicular bisector from AF, intersecting AO at G and OD at H. Lay off OJ equal to GO and OI equal to OH. With H as a center, draw a circular arc through C, and with I as a center draw a circular arc through D. With G as a center, draw a circular arc through A, and with J as a center draw a circular arc through B. These arcs will connect to form an approximate ellipse, as shown.

AUXILIARY VIEWS

In theory, there are only three regular multiview planes of projection: the vertical, the horizontal, and the profile. But as you have already seen, in multiview projection the plane of projection is always presumed to be between the observer and the object. This means that the vertical plane (for example) is presumed to be in one place for a front view and in a different place for a back view. Theoretically, it is the same plane; actually, however, there are two vertical planes—one the front view plane, the other the back view plane. It follows that, for a 6-view projection there are 6 regular planes: the front view and back view planes, the top view and bottom view planes, and the right side and left side view planes.

An auxiliary view is any view which is projected on a plane other than one of the regular 6. Refer back to figure 4-110. You recall that the line AB is oblique to all of the regular planes of projection, and therefore appears foreshortened in all 6 views. This

Figure 4-112.—Method of drawing an approximate ellipse with a compass.

means that the left side of the block cannot be shown in its true dimensions in any of the 6 regular views. To show the left side in its true dimensions, you would have to project it onto an auxiliary plane, parallel to the left side of the block.

Figure 4-113 illustrates the method of doing this. You select two adjacent views, one of which shows the edge of the surface which is to be projected in the auxiliary view, the other of which shows a dimension which will be required to lay out the auxiliary view. In this case, the front view and the left side view are the appropriate views.

You want to project the left side in its true dimensions; therefore, the projectors must be perpendicular to the left side, as indicated by the arrow. The auxiliary plane of projection must in turn be perpendicular to the projectors. The line marked "auxiliary plane and reference plane" represents an edge view of the auxiliary plane of projection. In theory, the projection is made on this plane, and then brought into the plane of the paper by rotation. You can draw the auxiliary plane and reference line any convenient distance away from the line AB.

You get the height of the auxiliary view by projecting points A and B, as shown. You get the width of the base by laying off this distance, as obtained from the left side view, from the reference plane line. You get the location of point B by measuring distance BO in the left side view, and laying this same distance off from the plane of reference, along the projector from B, in the auxiliary view.

The auxiliary plane line represents the edge of the auxiliary plane; the reference plane

Figure 4-113.—Projecting an auxiliary view.

Figure 4-114.—Alternative locations of reference plane line.

line represents the edge of the plane from which distances (as, in this case, the width of the block and the distance of B from the reference plane) are measured. In figure 4-113, the auxiliary plane line and the reference plane line coincide. This is not necessarily the case, however. You might have found it more convenient to locate the reference plane line as it is placed in the upper or the lower projection of figure 4-114. In both of these projections the auxiliary plane is located between the front view and the auxiliary view. These planes are not shown, and it is unnecessary to draw them.

The purpose of the auxiliary view shown in figures 4-113 and 4-114 is to show the left side of the block in its true dimensions. An auxiliary view may be required, however, simply to show how an object looks from a given angle of observation—and this angle may be any angle. In the upper left corner of figure 4-115 there is a cavalier projection of a block. It is desired that the right side of this block be shown as it would appear from the angle of observation indicated by the arrow. The right side as it would thus appear is shown in the auxiliary view. You can see that, while the thickness dimensions in the auxiliary view are true, the vertical

Figure 4-115.—Auxiliary view, showing object as seen from a particular angle of observation.

dimensions and the horizontal dimensions are all foreshortened. Once again, the amount of foreshortening works itself out as you project the auxiliary view.

DOUBLE AUXILIARY VIEWS

In figure 4-113 you were able to show the left side of the block in its true dimensions by making a single auxiliary projection. The reason you could do this was the fact that the surface you desired to project happened to be perpendicular to one of the three planes of projection (the vertical plane). Consequently, there was one multiview view (the front view, projected on the vertical plane) in which this surface appeared as a straight line. A single auxiliary view, projected from the surface as it appeared in the front view, showed the surface in its true dimensions.

In the upper left corner of figure 4-116 there is a cavalier projection of a block. The surface marked A is oblique to all three planes of projection. To show this surface in its true dimensions, you must first construct a primary auxiliary view, in which the surface appears as a straight line; and then from this view project a secondary auxiliary view, in which the surface appears in its true dimensions.

To construct the primary view, you must project the block onto a plane which is perpendicular to surface A. The reference line XX, shown on the front view, is drawn perpendicular to the line 1-3; it is therefore an edge view of a plane which is perpendicular to surface A. If you project the front view onto an auxiliary plane parallel to XX, you get a primary auxiliary view on a plane perpendicular to surface A.

In this primary view, surface A appears as a straight line. If you project the primary view onto a plane parallel to surface A, you will get a secondary view in which A appears in its true dimensions. The reference plane line X'X' in the secondary auxiliary view is drawn parallel to surface A as it appears in the primary view. You project the secondary view from the primary view by projectors drawn perpendicular to X'X'. You locate points on these projectors above and below X'X' by measuring the corresponding distance above and below XX in the front view from which the primary view was projected.

Figure 4-116.—Double, or primary and secondary, auxiliary views.

TRUE LENGTH OF A LINE BY AUXILIARY VIEW

The foregoing discussion has demonstrated the application of a basic rule to the effect that, if a line is parallel to a plane of projection, it will appear in its true length in a projection made on that plane. This rule may often be applied to determine the true length of a line which, because of the fact that it is oblique to all three of the standard planes of projection, appears foreshortened in all of the standard multiview views.

This method is illustrated in figure 4-117. In the upper left corner of this figure there is a cavalier projection of a triangular block. The line AB is oblique to all three of the regular planes of projection, and will therefore appear foreshortened in all of the regular multiview views. The true length of the line is shown in the small triangle at the upper right. It is the length of the hypotenuse of a triangle of which the length of the base is the length of AB as it appears in the top multiview view, and the altitude is the vertical distance of A above the lower horizontal line in the front multiview view.

The line AB is one of the edges of the surface ABC. You can get the true length of AB by projecting a partial auxiliary view of this surface from the view in which the surface ABC appears as a straight line. This view is the front view. You use an auxiliary plane parallel to the surface as it appears in the front view. The reference plane line X'X' is thus parallel. A line parallel to this one, located between the auxiliary view and the front view, would represent the edge of the auxiliary plane. There is no need to draw in the line.

The reference plane line X'X' represents the reference plane XX shown in the top view. Point A in the auxiliary view is located at the point of intersection between X'X' and the projector from A in the front view. Point B in the auxiliary view is located on the projector from B in the front view, at a distance from X'X' equal to the distance from B to XX in the top view. The line AB appears in its true length in the partial auxiliary view.

Figure 4-117.—Projecting a partial auxiliary view to get the true length of a line.

Figure 4-118.—Auxiliary section.

AUXILIARY SECTIONS

An auxiliary view may be a sectional rather than a surface view. In the upper left corner of figure 4-118 there is a cabinet projection of a block. It is desired to show the right side of this block as it would appear if the block were cut away on the plane indicated by the dotted

line, the angle of observation to be perpendicular to this plane. The desired view of the right side is shown in the auxiliary section, projected from a front view as shown. Because the auxiliary plane of projection is parallel to the cutaway surfaces, these surfaces appear in their true dimensions in the auxiliary section.

REVOLUTIONS

You may have a tendency, at first, to confuse a revolution with an auxiliary view, but there is a definite difference between the two. An auxiliary view is a view on a plane other than one of the regular multiview planes of projection. A revolution is always projected on a regular plane of projection. What distinguishes a revolution from the equivalent normal multiview projection of an object is the fact that the revolution shows the object as it would appear if it were revolved on an axis perpendicular to one of the planes of projection.

Figure 4-119.—(A) Multiview view of block in position. (B) Multiview view of block revolved 30°. on axis perpendicular to vertical plane.

Figure 4-120.—(A) Revolution on axis perpendicular to horizontal plane. (B) Revolution on axis perpendicular to vertical plane.

Figure 4-119(A) shows a 3-view multiview projection of a block. The block in these views is in normal position, with the top and bottom surfaces parallel to the horizontal plane of projection, the front and back surfaces parallel to the vertical plane, and the side surfaces parallel to the profile plane.

Figure 4-119(B) is a 3-view multiview projection showing the block as it would appear if it were revolved 30° on an axis perpendicular to the vertical plane of projection. Because the front and back faces of the block remain perpendicular to the horizontal and profile planes of projection, the thickness dimensions in the top and side views remain true. Because the top and bottom surfaces are now oblique to the horizontal plane of projection, the lengthwise dimensions in the top view are all foreshortened. Because the side surfaces are now oblique to the profile plane of projection, the vertical dimensions in the right side view are

2. The maximum emission limit of the cathode.

3. The maximum beam current that can be focused without excessive heating of the tube elements due to the currents into these elements.

TUNABLE AMPLIFIER.—Using the TWT, it is possible to obtain high values of gain over a broad tuning range by varying the slow wave voltage. Use of a narrowband TWT decreases the danger of oscillation and permits greater gain to be obtained, but over a restricted frequency range. The wideband TWT permits high values of gain to be obtained over a greater range of frequencies, but the danger of oscillation is increased.

IF AMPLIFIER.—All pulse amplifiers require wide bandpass characteristics, and the more narrow the pulse, the wider the passband required of the amplifier. The TWT seems to be especially well adapted for use in this type circuitry, and has been used successfully as an IF amplifier at 3,000 megacycles, replacing the complex (and frequently troublesome) assemblies normally used for that purpose.

INPUT AMPLIFIER.—When used as the input amplifier of a radar receiver, the TWT must be able to respond linearly to input power levels over a wide range. Due to the limiting action of the TWT, however, modulated inputs with high power levels result in distortion. This disadvantage may be decreased by use of a varying helix voltage which extends the saturation point beyond the largest anticipated input. (This method is not applicable to phase sensitive radar systems.)

Low noise TWT's are especially useful in the input circuits of radar receivers because of the low noise figure throughout the life of the tube, and the additional protection of the crystal mixer following the TWT.

MODULATION.—In traveling wave tubes operating under CW conditions, the broadband circuit has an essentially constant phase angle. Since the interaction circuit is electrically quite long (usually at least 10 wavelengths), a slight variation in beam velocity can produce an appreciable variation in phasing at the output end of the structure. This is known as PHASE MODULATION. The allowable limits of variation are determined by the circuit.

AMPLITUDE MODULATION of the TWT may be accomplished by merely varying the potential applied to the electrode which controls the beam current. Generally, high percentages of modulation may be obtained from this method.

PULSE MODULATION is accomplished by pulsing the beam accelerating potential, or by pulsing the cathode with respect to the other electrodes. Pulsed tubes normally operate at the same potentials as would be used for the same tube operating under CW conditions. Peak power output in pulsed circuits may be increased only by increasing beam current, but this is practical only through comparatively narrow limits.

SAWTOOTH PHASE MODULATION results from applying a sawtooth wave to the slow wave element. The phase of the signal is continuously advanced, simulating an increase in frequency. This method is effectively the basis of single sideband modulation. It may also be used to simulate Doppler effect.

FREQUENCY SHIFTING.—This is accomplished in the same manner as phase modulation, the only difference being in the application and output circuitry. If the slow-wave-to-cathode impedance is low at the desired shift frequency, it may be possible to drive the cathode along in order to obtain the required output. Additional changes in phasing result from these variations in beam current.

DYNAMIC PHASE SHIFTING in the TWT occurs whenever amplitude or pulse modulation is the result of changing the beam current, the slow wave circuit voltage, or the anode voltage.

STATIC PHASE SHIFTING may occur as a result of differences in the effective lengths of the slow wave circuits or of the input and output coupling devices.

LIMITING.—Due to the saturation characteristics of the TWT, relatively constant output power may be obtained over a wide range of input power levels. By a slight modification of the basic TWT, this limiting action may be significantly increased. Use of two TWT's connected in cascade permits the level of output power to be held constant within 0.5 db over a 50-db range of input power and a 25-percent frequency variation.

AUTOMATIC GAIN CONTROL (AGC).—The limiting action of the traveling wave tube may be enhanced by the use of a feedback voltage applied to the electrode which controls beam current. Such a configuration is called an automatic gain control circuit, and is used when a constant power output level is required.

Oce 85
989

all foreshortened. Again the amount of foreshortening works itself out as you project the views.

For the revolution shown in figure 4-119(B), you revolved the object on an axis perpendicular to the vertical plane of projection. You could have revolved it on an axis perpendicular to the horizontal plane, which would have resulted in the revolution shown in figure 4-120(A); or you could have revolved it on an axis perpendicular to the profile plane, which would have produced the revolution shown in figure 4-120(B).

REVOLVED SECTIONS

A common use of the revolution is the revolved section illustrated in figure 4-121. At the top of this figure there is a cabinet projection of a triangular block. You can show everything that needs to be shown about this block in a 2-view multiview drawing, by including a revolved section in the front view, as shown. You first assume that the bar is cut by a plane perpendicular to the long axis; you then revolve the resulting section 90° on an axis perpendicular to the horizontal plane of projection.

Figure 4-121.—Revolved section.

SECTIONING TECHNIQUES

Hidden and Visible Lines

A section view is called for when the internal structure of an object cannot be satisfactorily shown in a surface view by means of hidden lines. In the upper part of figure 4-122 there is a cabinet projection of a pulley. The same object is shown below in a 2-view multiview projection. The internal structure of the pulley is shown by the hidden lines in the top view, but these lines do not present a very clear picture.

You can show the internal structure much more clearly by projecting a section view, as shown in figure 4-123. Note that hidden lines behind the plane of projection are omitted in the sectional view. These lines are omitted by general custom, the custom being based on the fact that the elimination of hidden lines is the basic reason for making a sectional view. However, lines which would be visible behind the plane of projection must be included in the section view.

Figure 4-122.—Internal structure shown by hidden lines.

Figure 4-123.—Internal structure shown more clearly by section view.

Figure 4-124.—Half section.

Figure 4-125.—Partial or broken section.

Full and Half Sections

The section shown in figure 4-123 is called a full section, because the cutting plane passes entirely through the object and divides the object into two equal halves. Now, the object shown in figure 4-123 is a symmetrical object, meaning that one-half of the object is identical with the other. This being the case, you could have used a half section like the one illustrated in figure 4-124. This half section consists of one-half of a full section. Because the other half would be identical, it is unnecessary to include it.

Note that you use the horizontal center line, rather than a visible line, to indicate the dividing line between the sectioned and the unsectioned part of the section view. If you used a visible line, the line would indicate an edge which is nonexistent.

Partial Sections

A section which consists of less than a half section is called a partial section. A partial section is illustrated in figure 4-125. Note that here you use a break line to indicate the dividing line between the sectioned and the unsectioned part. For this reason a partial section is often called a broken section.

Section Lining Techniques

The lines drawn on a sectional surface always serve one purpose: to indicate the limits of the sectional or cutaway surface. They may serve another purpose as well: to indicate the kind of material of which the object is made. For the second purpose, a specific type of section lining is used.

If the section lining is intended to indicate type of material, a series of parallel lines, drawn at a 45° angle to the horizontal and about 1/16 in. apart, indicate cast iron. On drawings on which the section lining is not intended to indicate type of material, however, the symbol for cast iron is used for all section lining. The symbol, called diagonal hatching, is shown at the left in figure 4-126.

Figure 4-126 shows a set of simplified sectioning symbols, as prescribed in MIL-STD-1B.

Angle of Diagonal Hatching

On a normal multiview section view, diagonal hatching should be drawn at a 45-degree angle to the horizontal, as shown in figure 4-127(A). If two adjacent surfaces are shown, the hatching should be inclined in opposite directions, as shown in figure 4-127(B). If still a third surface is included, it should be hatched at an angle of 30°, as shown in figure 4-127(C).

Note that the hatching lines on one surface are not permitted to meet those on an adjacent surface.

Diagonal hatching on an auxiliary section should be drawn at a 45-degree angle to the horizontal as the horizontal exists in that particular view. In the upper part of figure 4-128 there is a cavalier projection of a block. Below there is an auxiliary section showing the block as it would appear if it were cut along the plane indicated by the dotted line, the angle of observation being perpendicular to the plane. With regard to the auxiliary section, the horizontal is indicated by the projectors. You therefore draw the diagonal hatching at 45° to the projectors.

Figure 4-126.—Section conventions.

Figure 4-127.—Diagonal hatching on separate sectional surfaces shown in normal position.

In a revolution or other view of an object in other than normal position, diagonal hatching should be drawn at a 45-degree angle to the horizontal or vertical axis of the object as it appears in the drawing. In the upper part of figure 4-129 there is a cabinet projection of a block. Below there is a 3-view multiview projection of the block revolved 15° on an axis perpendicular to the horizontal plane of projection. The top view is a section view; the diagonal hatching is drawn at 45° to the horizontal axis of the drawing.

Figure 4-128.—Angle of diagonal hatching on auxiliary section.

Figure 4-129.—Angle of diagonal hatching on a revolution.

ISOMETRIC DRAWING TECHNIQUES

BOX CONSTRUCTION

A rectangular object—that is, one on which all the surfaces are rectangular, with each surface perpendicular to the adjacent surfaces—can be easily drawn in isometric by the procedure known as box construction. In the upper part of figure 4-130 there is a 2-view normal

multiview projection of a rectangular block. An isometric drawing of the block is shown below. You can see how you build the figure on the isometric axis, and how you lay out the dimensions of the object on the isometric drawing. Because you laid out the identical dimensions, it is an isometric drawing rather than an isometric projection. To make an isometric projection, you would reduce each dimension to the scale of 0.8165:1, or about 4/5.

NONISOMETRIC LINES

Each line in the isometric drawing shown in figure 4-130 is equal in length to the same line as it appears in the normal multiview projection. The reason is the fact that each line in the isometric drawing is an isometric line—meaning, a line that forms the isometric angle (35° 16') with the plane or projection. Any isometric line will appear in its true length in a full-scale isometric drawing. In a full-scale isometric projection, it will appear scaled down to about 4/5.

If you examine the isometric drawing, you will note that each line in the drawing is parallel

Figure 4-130.—Box construction.

Figure 4-131.—The line AB is a nonisometric line.

to one or another of the legs of the isometric axis. An alternate definition of an isometric line, then, is a line which, in an isometric projection or drawing, is parallel to one of the legs of the isometric axis.

You will also notice that each line in the isometric drawing is a line which is a normal line in the normal multiview projection. A normal line, you recall, is a line which, in a normal multiview projection, is parallel to two of the planes of projection and perpendicular to the third. Still another definition of an isometric line, then, is a line which is a normal line in a normal multiview projection of the object.

From these definitions of an isometric line, the definition of a nonisometric line may be constructed. A nonisometric line is a line which,

in an isometric projection or drawing, forms an angle of other than 35° 16' with the plane of projection. It is a line which, in an isometric drawing or projection, is not parallel to any one of the three legs of the isometric axis. It is a line which is not a normal line in a normal multiview projection of the object. Finally, it is a line which, on a full-scale isometric drawing, does not appear in its true length, and which, on a full scale isometric projection, does not appear scaled down to the scale of 0.8165:1, or about 4/5.

In the upper part of figure 4-131 there is a 2-view normal multiview projection of a block. Though the line AB is parallel to the horizontal plane of projection, it is oblique to both the vertical and the profile planes. It is therefore not a normal but an oblique line in the multiview projection, and it will be a nonisometric line in an isometric projection or drawing of the same object.

The line AB appears in its true length in the top multiview view, because it is parallel to the plane of that view (the horizontal plane). But it will appear as a nonisometric line, and therefore not in its true length, in an isometric drawing. It follows that you cannot transfer AB directly from the multiview projection to the isometric drawing. You can, however, transfer directly all the normal lines in the multiview projection, which will be isometric lines, appearing in their true lengths, in the isometric drawing. When you have done this, you will have constructed the entire isometric drawing, exclusive of line AB, and of its counterpart on the bottom face of the block. The end points of AB and of its counterpart will be located, however, and it will only be necessary to connect them by straight lines.

ANGLES IN ISOMETRIC

In a normal multiview view of an object an angle will appear in its true size. In an isometric projection or drawing, an angle never appears in its true size. Even an angle formed by normal lines, such as each of the 90-degree corner angles of the block shown in figure 4-131, appears distorted in isometric.

The same principle used in transferring a nonisometric line is used to transfer an angle in isometric. In the upper part of figure 4-132 there is a 2-view multiview projection of a block. On the top face of the block the line AB makes a 40-degree angle with the front edge. The line AB is an oblique (that is, not normal) line, which will appear as a nonisometric line in the isometric drawing. You locate the end points of AB on the isometric drawing by distances measured along normal lines on the multiview projection, and laid off along the corresponding isometric lines on the isometric drawing. The ange which measures 40° on the top multiview view measures only about 32° on the isometric drawing. Note, however, that it is labeled 40° on the isometric drawing. This is because it is, actually, a 40-degree angle, as it would look on a surface placed at the isometric angle of inclination.

CIRCLES IN ISOMETRIC

A circle which appears in a normal multiview view will appear as an ellipse in an isometric drawing of the same object. This is illustrated in figure 4-133. The circle which appears in the top multiview view appears as an ellipse in the isometric drawing. The top view intersecting vertical and horizontal diameters form the conjugate axes of the ellipse in the isometric drawing.

Figure 4-132.—Drawing an angle in isometric.

If an accurate ellipse is required you can draw the ellipse by the conjugate-axis method described earlier. However, in a case of this kind, an approximate ellipse, drawn with a compass, is usually satisfactory. Notice first, in figure 4-133 that the intersecting conjugate axes of the isometric ellipse always parallel two of the legs of the isometric axis. To draw an approximate isometric ellipse, first draw the circumscribing parallelogram ABCD, by drawing lines at the ends of each conjugate axis, parallel to the other axis, as shown in figure 4-134. Then draw the approximate ellipse as follows.

Draw the diagonal AC. Draw straight lines from the midpoint of AB and the midpoint of BC to D. The points of intersection (0 and 0') between these lines and the diagonal AC are centers for the end arcs of the approximate ellipse. Points B and D are centers for the intermediate arcs.

Figure 4-134.—Method of drawing approximate ellipse on isometric conjugate axis.

Figure 4-133.—Circle on a normal multi-view view appears as ellipse in isometric drawing.

Figure 4-135.—Method of drawing a noncircular curve in isometric.

Figure 4-136.—Varying position of isometric axis varies view of the object.

NONCIRCULAR CURVES IN ISOMETRIC

A line which appears as a noncircular curve in a normal multiview view of an object will obviously be a nonisometric line in an isometric drawing of the same object. To transfer such a line to an isometric drawing, you must plot a series of points by measurements made along normal lines in the multiview view and transfered to corresponding isometric lines in the isometric drawing.

In the upper part of figure 4-135 there is a 2-view multiview projection of a block with an elliptical edge. To make an isometric drawing of this block, draw the circumscribing rectangle on the top multiview view, lay off equal intervals as shown, and draw perpendiculars at these intervals from the upper horizontal edge of the rectange to the ellipse. Then draw the rectangle in isometric, as shown below, and plot a series of points along the elliptical edge by laying off the same perpendiculars shown in the top multiview view. Fair in the line of the ellipse through these points with a french curve.

ALTERNATE POSITIONS OF ISOMETRIC AXIS

Up to this point the isometric axis has been used with the lower leg vertical. The axis may, however, be used in any position, provided the angle between adjacent legs is always 120°. Figure 4-136 shows how varying the position of the axis varies the view of the object.

DIAGONAL HATCHING IN ISOMETRIC

Diagonal hatching on a sectional surface shown in isometric should have the appearance of making a 45-degree angle with the horizontal or vertical axis of the surface. If the surface is an isometric surface (one which makes an angle of 35° 16' with the plane of projection), lines drawn at an angle of 60° to the horizontal margin of the paper, as illustrated in figure 4-137, present the required appearance. For diagonal hatching on a nonisometric surface, you must experiment to determine the angle which presents the required appearance.

OBLIQUE DRAWING TECHNIQUES

In an isometric drawing or projection of a rectangular object, no face of the object is parallel to the plane of projection. In an oblique projection or drawing of a rectangular object, one face (usually the most prominent or most important) is parallel to the plane of projection. Consequently, the axis for an oblique drawing has two legs (called the front axes) perpendicular to each other, and a third (called the receding axis) which may be drawn at any convenient angle.

Figure 4-137.—Diagonal hatching in isometric.

Figure 4-138.—Cavalier projection. Distances along front axes and along receding axis are all true.

TRUE AND FORESHORTENED DIMENSIONS

In the upper part of figure 4-138 there is a 2-view multiview projection of a rectangular board. Below there is a cavalier projection of the same board. The figure is built on the indicated axis, two legs of which are perpendicular to each other. Distances along the front axes and the receding axis are all true, as indicated.

The figure shown in cavalier projection appears to be elongated along the receding axis. In figure 4-139, the same object is shown in cabinet projection. In this projection the appearance of distortion along the receding axis is reduced by reducing measurements along this axis by one-half, as shown. Distance along the front axes are true.

IRREGULAR LINES

An irregular line in an oblique drawing is a line which would be an oblique line in a normal multiview projection, or a nonisometric line in an isometric drawing, except that in an oblique drawing there are no irregular lines

Figure 4-139.—Cabinet projection. Distances along front axes true; distances along receding axis reduced by one-half.

Figure 4-140.—Cavalier projection of irregular line.

Figure 4-141.—Transferring an angle in oblique.

on the surface which is parallel to the plane of projection. In the upper part of figure 4-140 there is a 2-view multiview projection of a block; the line AB is an irregular line which, like a nonisometric line, will not appear in its true length in an oblique projection. To transfer the line you proceed just as you do with a non-isometric line: you draw the projection by transferring measurements taken along regular lines, and this locates the end points of the irregular line. Figure 4-140 shows the cavalier projection of an irregular line. The procedure for a cabinet projection would be the same, except that all measurements along the receding axis would be reduced by one-half.

ANGLES IN OBLIQUE

In an oblique projection an angle on the surface which is parallel to the plane of projection will appear in its true size; an angle on any other surface will not. In the upper part of figure 4-141 there is a 2-view multiview projection of a block. There is a 30-degree angle on the top face and another on the front face. In the cavalier projection below, the angle on the front face still measures 30°; that on the top face measures only about 9° You transfer the top face angle just as you do an angle in isometric: by locating the end points of the line by measurements along regular (the equivalent of isometric) lines.

CIRCLES IN OBLIQUE

In an oblique projection, a circle on the surface parallel to the plane of projection will appear as a circle. A circle on any other surface will appear as an ellipse, as illustrated in figure 4-142. In the upper part of this figure there is a 2-view multiview projection of a block with

Figure 4-142.—Cavalier projection of a circle on a receding surface.

Microwave Frequency Generators

If a small part of the output is fed back to the input (through a directional coupler, a resonant cavity, and a phase shifter), stability of an oscillator can be improved. The total RF phase shift must be controlled so as to assure regenerative phasing at the input, and loop loss must be controlled in order to provide the proper magnitude of feedback signal. These requirements may be met by incorporation of a variable phase shifting network and a variable attenuator.

Phase shifting in the circuit may result from any of the following (or any combination of them):

1. Transmission line delays. These include phase shifts due to the length and the distributed constants of the transmission line system, the helix structure, the couplers, etc.
2. Resonant cavity or filter delays.
3. Electronic phase shifting resulting from any changes in the potentials applied to the electrodes.

Use of a filter having a wide bandwidth and low losses allows electronic tuning by merely varying the helix voltage. If the filter is of a narrowband type, tuning may be done manually.

As the output of a TWT approaches its saturation point, frequency harmonics are produced. Conversion gains of about 10 db can be obtained when the tube is used as a frequency doubler, with somewhat less gain for higher order harmonics.

BACKWARD WAVE OSCILLATOR

The "M" type backward wave oscillator (M-BWO) is a wideband, high powered, highly efficient and reliable source of microwave power. It offers high speed, half-octave electronic tuning by variation of a single control voltage. Its most extensive application to date has been in ECM barrage and spot noise jamming.

During World War II, the magnetron, with mechanical tuning, was the workhorse of the microwave electronic warfare equipment. However, because wide and rapid tuning requirements began to develop for both radar and countermeasures, wideband electronic tuning of high powered microwave oscillators became desirable.

The development of the voltage tunable magnetron and the principle of traveling wave interaction in linear beam tubes stimulated work on crossed field traveling wave devices. This led to the development of the CARCINOTRON and M-BWO.

The M-BWO has become an excellent microwave ECM transmitter tube because of the following characteristics:

1. The advantage of the M-BWO's voltage tuning over mechanical tuning.
2. The tube's high power and efficiency.
3. Its versatility.
4. Its economy of size and weight.

APPLICATIONS

Noise jamming is a brute force method of jamming which supplies sufficient noise to radar receivers to make it difficult to distinguish target echoes. The noise RF power is obtained by frequency and/or amplitude modulating the M-BWO with a noise source and a sine wave source. The noise bandwidth can be varied about the operating frequency, thus providing a high degree of flexibility in terms of watts per megacycle versus bandwidth. The two basic modes of operation are spot or narrowband jamming, and barrage or wideband jamming.

BASIC PRINCIPLES

The M-BWO is a voltage tunable microwave power generator using the interaction of a ribbon beam traveling near a frequency selective delay line. Electric and magnetic fields are maintained at right angles to each other and to the direction of the beam. The beam velocity is substantially the same as the phase velocity of a wave component traveling along the delay line. By this means, energy is transferred from the static field to the RF field. In the M-BWO, the RF energy travels in a direction opposite to that of the electron beam.

In most practical tubes, the interaction space is ring shaped. Figure 12-18 (A) shows a cross section of a typical tube and shows the path of the electron beam and the RF energy under oscillating conditions. Figure 12-18 (B) illustrates a three-dimensional cross sectional view of an earlier M-BWO.

The M-BWO is a member of the traveling wave tube family described earlier in this chapter, having in common with it the slow wave device, or delay line, and the bunching of electrons in the beam. The M-BWO differs from the TWT in several ways, including the use of the crossed magnetic field. You will probably recall that crossed magnetic fields are also used in the magnetron.

990

a circle on its upper face. Below there is a cavalier projection, in which the circle appears as an ellipse. Each of the conjugate diameters of the ellipse is equal to the diameter of the circle.

Here again an approximate ellipse, drawn with the compass, is generally considered satisfactory. You cannot use the method used for drawing an approximate ellipse in isometric (fig. 4-134), however, because that method can be used only when the conjugate axes of the ellipse are parallel to two legs of the isometric axis.

Figure 4-143 shows a method of drawing an approximate ellipse in cavalier projection. Draw the circumscribing parallelogram ABCD by drawing lines at the ends of each axis, parallel to the other axis. Erect perpendicular bisectors from AB, BC, CD, and DA. These bisectors intersect each other at X and X' and at Y and Y' X and X' are centers for the interemdiate arcs of the approximate ellipse; Y and Y' are centers for the end arcs.

The method (called the four-center method) is basically the same as that illustrated in figure 4-134. It happens, however, than in an isometric circumscribing parallelogram perpendicular bisectors from the sides always intersect at corners of the parallelogram. This is not usually the case in a cavalier parallelogram.

The situation is a little different in a cabinet or other oblique projection in which measurements along the receding axis are reduced to lessen the appearance of distortion. In the upper part of figure 4-144 there is a 2-view multiview projection of a block with a circle on the right side. Below there is a cabinet projection, in which the circle appears as an ellipse. Note here, however, that the horizontal conjugate diameter of this ellipse is only one-half the length of the vertical conjugate diameter. For this reason, you must draw this ellipse by the method described earlier for drawing an ellipse on conjugate diameters. The four-center method of drawing an approximate ellipse (used in isometric drawing, fig. 4-134 and cavalier projection fig. 4-143) will work only on an ellipse with conjugate diameters which are equal in length.

PERSPECTIVE PROJECTION

Perspective drawings constructed by perspective projection are one-view drawings. While they do not show the object in its true shape and dimensions, they do show how the object looks to an observer and, as a consequence, they are easier to comprehend at a glance than drawings made according to orthographic projection. For this reason, perspective projection is often used for exploded views of objects to show all the different parts and their relationship to each other. Perspective projec-

Figure 4-143.—Method of drawing approximate ellipse for cavalier projection of a circle on a receding surface.

Figure 4-144.—Circle on receding surface shown in cabinet projection.

tion is also sometimes used for architectural renderings of proposed structures to show how the structures will look when they are completed.

Perspective projection drawings requiring very accurate projection are usually done by working from orthographic views of the object. For purposes of illustration, however, this type of painstaking projection is not necessary. Many illustrators do not use the methods of perspective projection at all, making their perspective drawings by approximating the positions of various planes. But, unless you are a very keen observer and have had considerable practice, you are likely to commit some rather ridiculous errors if you try to draw perspective illustrations by guesswork alone. A few simple rules and a few pains taken in constructing a scene or an object will help you make better drawings.

ONE-POINT PERSPECTIVE

Figure 4-145 is a one-point perspective projection of a cube from a top and side view in orthographic projection. The technical terms which will be used in discussing perspective projection are illustrated in the figure.

Notice that the picture plane becomes a line in the top and side orthographic views. Projectors from the corners of the top view are drawn converging toward the station point but, from the points where the projectors, or visual rays, pierce the picture plane, parallel projectors are drawn down to the perspective view.

Figure 4-145.—One-point perspective drawing obtained from orthographic views.

Figure 4-146.—Position of the station point at right or left of center in parallel perspective drawings.

The station point for the side view is actually the same station point as that shown for the top view. It is, therefore, the same horizontal distance from the cube, but its elevation shows the height of the station point above the level of the cube. The picture plane in the side view is also the same distance from the cube as in the top view, and the ground line in this view, on which the picture plane rests, defines the ground line of the picture plane in the perspective drawing.

In the side view, projectors are drawn converging to the station point, and at their piercing points on the picture plane, parallel horizontal projectors are drawn to the perspective drawing. The intersection point of a projector from a corner of the cube in the top view with the projector from the same corner in the side view locates the corner in the perspective drawing.

Notice that the center of vision in this drawing is located directly above the station point in the perspective drawing and on the same line with the station point for the side view of the cube. This line is the eye level line. It is also the horizon line for the drawing.

The center of vision defines the point at which all lines perpendicular to the picture plane in the perspective drawing converge. It also coincides with the vanishing point in one-point perspective drawings. The fact that there is only one vanishing point in this type of perspective drawing gives it its name. It is also called parallel perspective because the front face of the object is parallel to the picture plane.

In parallel perspective drawings, the center of vision is not necessarily centered on the object. It may fall to one side or the other as

shown in figure 4-146. However, when the front face is parallel to the picture plane and the center of vision is at one side of the drawing, there will necessarily be some distortion. Actually, the drawing becomes an oblique projection and not a true perspective drawing. Notice that in order to make such a drawing, the object must be considered as resting with its front face against the picture plane. If this were not so, converging projection lines from the corners of the front face would alter its appearance so that it would no longer appear to be parallel with the picture plane. In fact, as you will see, it would then become a two-point, rather than a one-point, perspective drawing.

TWO-POINT PERSPECTIVE

Two-point perspective is the most commonly used method for making perspective drawings. In two-point, or angular perspective, the object is considered as sitting at an angle to the picture plane. In the perspective drawing of such an object, there are 2 sets of horizontal edges converging toward 2 different vanishing points on the eye level or horizon line. The parallel lines which slope to the right will vanish at a point in the distance called the right vanishing point (VPR) and those that slope to the left at a point called the left vanishing point (VPL). (See fig. 4-147.)

In the figure, the top orthographic view of the block was drawn first. The position of the picture plane was then determined.

When the corner of the object rests against the picture plane, the vertical line representing the corner in the perspective drawing will be full size. In one-view perspective, the front face is full size in the perspective drawing if it rests against the picture plane. In any perspective drawing, the comparative sizes will be reduced proportionately as the distance is increased between the picture plane and the object.

Once the picture plane was established, the station point for the top view in figure 4-147 was located approximately opposite the center of the block. The distance from the station point to the object should not be less than twice the width of the object.

When this rule is neglected, a distorted appearance may result in the perspective drawing. There is a cone of about 30° in which the human eye sees clearly. For this reason, the angle formed by the lines of sight from the sides of the object to the station point should not exceed 30°. In no case, even when the

Figure 4-147.—Two-point or angular perspective.

Figure 4-149.—Two-point perspective drawing made without using an elevation of the object.

elevation is not used, the various heights cannot be found directly. However, the bottom of the block may be located, as shown in figure 4-149 by drawing lines to the vanishing points from the point selected as the near corner.

Now if the perspective height of any one vertical line can be determined, the height of the other verticals can be found automatically. This is easy to do when one edge of the object rests against the picture plane. This edge will then appear in its true height in the perspective view. If you have the dimension for this height in the orthographic projection, you can transfer that dimension directly to the perspective view. Lines drawn to the vanishing points from this top corner will locate the top of the two sides, and lines drawn to the vanishing points from the far corners on these sides will complete the drawing of the block.

When the front edge of the subject does not rest against the picture plane, it is necessary to use some other dimension. Since the end of the block is square it is possible to find the perspective length of a horizontal line and use this dimension for the edge of 1-5. This is done, by drawing a line parallel to the picture plane from 1, measuring a length of this line equal to 1-3, and drawing a line converging on the station point to the picture plane from the end of this line.

This length can then be transferred to the front edge of the perspective view and the view completed as shown in figure 4-149. To check the accuracy of this method, compare figure 4-149 with 4-147. You will find that, since the station point, horizon level, and the bottom of the cube correspond, the two perspective views are similar. It is possible to make them correspond exactly.

In figure 4-149 the bottom of the front edge of the block has been placed autocratically at a certain point. Actually it could have been placed on the vertical projection from the cube at any desired point. Thus, the perspective view may be drawn below the eye level, or it may be drawn at eye level or above it, as shown in figure 4-150.

However, if the object is placed too high above the eye level or too low below it, the effect will be one of distortion. A block drawn in these positions will cease to look right as shown in figure 4-151. When the station point is too close to the object, there will be a similar distortion. The angle indicated in the figure should never be less than 90° and preferably not less than 100°.

Figure 4-150.—A. Object on eye level. B. Object above eye level.

Figure 4-151.—A. Object placed too high above eye level.
B. Object placed too low below eye level.

To overcome distortion such as that illustrated in figure 4-151, the station point may be moved further from the object or the picture plane may be tilted so that a third vanishing point is needed for the third set of parallel lines in the drawing.

MEASUREMENTS IN TWO-POINT PERSPECTIVE

In drawing objects with compound shapes, a series of cubes may be used. If you draw a cube in two-point perspective, you can easily divide the perspective views of the sides of the cube into halves and again into quarters by using diagonals, as shown in figure 4-152A.

The diagonals of the square sides establish the centers of these sides. Verticals erected through each center, divide the side into halves. In order to divide the squares into quarters, find the center of a vertical side and draw lines from this point receding toward the vanishing points. This establishes the centers of the vertical edges. Now draw a diagonal in one of the quarters so established. This diagonal will cross the diagonal of the large square. Finally erect a vertical through the point established by the intersection of these two diagonals. As you can see, this process of division can be carried on as far as necessary to establish the required division points on a horizontal edge or within the square itself.

It is also possible by using diagonals to add to the sides of the cube in multiples of 2, 4, 8, etc., as shown in figure 4-153. First, the center of the square side is found and a vertical and horizontal are drawn through this center. The horizontal is extended beyond the side of the cube toward the vanishing point and the horizontal edges of the side are also extended toward this point, as shown in figure 4-153A.

A diagonal drawn from the center point on the lower horizontal edge of the square through the center point on the far edge will intersect the extension of the top edge as shown in figure 4-153B. A vertical dropped from this intersection will add the equivalent of a half to that side. As you can see, this process can be continued as many times as necessary, and the sections so established can be divided in turn.

Figure 4-152.—Using diagonals to establish divisions on a line or a plane in perspective.

Figure 4-153.—Using diagonals to multiply areas.

Figure 4-154.—Finding the outside dimensions of a bookcase in perspective.

Now suppose you are asked to draw in perspective a bookcase 36 inches high, 24 inches wide, and 12 inches deep. Since the 36 inches can be divided into 18 inches or 9 inches but not into 24 or 12, it will be better to make the basic cube 24 inches, which can easily be divided into 12 inches and to which 12 inches can be added. In figure 4-154B, these dimensions have been established. Note that the same method used for multiplying areas in a horizontal direction, shown in figure 4-153, may be applied to multiplying them in a vertical direction.

Suppose that the bookcase is constructed of boards which are 1 inch thick. The top shelf is 8 inches high—that is, the upper front edge is 9 inches from the top of the bookcase, and the lower shelves are 12 inches high—that is, 13 inches including the width of one shelf—with the lowest shelf resting on the floor. Notice that 9 inches is one-fourth of the total height of the bookcase, which should make it easy to find this dimension. A diagonal may be used to create a 36-inch square, as shown in figure 4-155A, and diagonals may be used to locate the top shelf, as shown in figure 4-155B.

Figure 4-155.—Locating the shelves of the bookcase.

Figure 4-156.—Locating the rear edges of the shelves.

If either of the verticals bounding this shelf can be easily divided into nine of some convenient unit, such as an eighth of an inch, the width of the board can be found for that vertical, as shown in figure 4-155C. Since the bottom of the front edge of the second shelf is one-half the remaining distance, this dimension may be located by using dividers. The width for the horizontal shelf boards may be easily estimated. (See fig. 4-155D.)

Next work out the rear edge of each shelf, starting by finding the front edge of the backboard. This will be one inch from the rear edge of the bookcase itself. The measurement may be approximated. Mark a point one inch from the back of the bookcase on each of the lines. From these points, draw lines toward the right vanishing point to define the rear edges. (See fig. 4-156.)

To define the inside edges of the shelves at the right side of the bookcase, draw lines toward the left vanishing point from the points where the top edges of the front of the shelves meet the right side of the bookcase. Where these two sets of lines intersect, erect a vertical.

When the problem consists of finding equal division points of a plane in perspective, such as a line of telephone poles along a road or equally spaced divisions on a wall or a floor, and the spacing of these points is known, the problem may be solved as shown in figure 4-157. Since the points are parallel on the object, they will have a common vanishing point. If the plan view is used, the points may be projected to the picture plane in that view as shown in figure 4-157A. Then they are

Figure 4-157.—Measurement of horizontal points that are equally spaced.

projected to the picture plane in the perspective view, and lines are drawn toward the vanishing point.

If no plan view is used, a horizontal line is simply drawn, as shown in figure 4-157B and the points spaced off on this line. Notice that this method of finding the position of equally spaced points on a line is very much like the common method of dividing a line into equal spaces.

VANISHING POINTS FOR INCLINED LINES

Just as horizontal planes vanish at the horizon line and horizontal lines vanish at a point on the horizon line, so inclined planes will vanish on a line and inclined lines which are parallel on the object will vanish at a point on this line. The vanishing line for inclined planes will always be a vertical passing through one of the two vanishing points, while the vanishing point for parallel inclined lines will fall somewhere on this line.

In figure 4-158, the vanishing points of 3 pairs of parallel lines defining 3 inclined planes are found on the vertical line erected for VPR. In the drawing, a plan view of the object was used and the station point was located. Then the vanishing points were found by the method shown in figure 4-148.

Points on horizontal and vertical planes can then be found by methods previously described. That is, lines are drawn converging on the station point from these points in the plan view to the picture plane and from the picture plane they are projected to the perspective view. Since the front edge of the plan view rests against the picture plane, the length of this edge is the same as it is in the orthographic drawing and can be projected directly from the elevation at right. From this edge, lines can be drawn converging on the left and right vanishing points.

However, the points on the inclined planes are not so easily found. In order to locate point A, it can be assumed to be moved forward to the picture plane, as shown by faint crosses; and measuring lines drawn down from the picture plane. The true height can then be projected from the elevation to intersect these lines. Lines are drawn from these points to the vanishing points. Point A is then established for the perspective drawing as the point where these receding lines cross. The other points in question can be found in the same way.

A line drawn from A' through A in the perspective drawing to the vertical passing through the right vanishing point establishes the vanishing point for all other inclined lines parallel with this one.

The vanishing point of the edges of inclined planes is found in the same way since the lines defining them are parallel lines on the object.

MEASURING LINES

Measuring lines are often used in architectural drawings to locate points which do not fall in the picture plane. In the drawing in figure 4-159 the station point, ground line, and picture plane were located first. The eye level, or horizon line was drawn about 5 feet 6 inches on the selected scale above the ground line, and the vanishing points were located on it.

(A)

(B)

Figure 12-18.—Typical M-type backward wave oscillator.

The principle of traveling wave interaction is basic to all crossedfield devices. The major objective is to convert electrical energy from static (d-c) form to electromagnetic energy in extremely rapid (microwave frequency) alternating form. The electron is used for this

Figure 4-158.—Finding the vanishing point of inclined lines.

Figure 4-159.—Measuring lines in two-point perspective drawings.

Next the plan and elevation were drawn to the same scale. In the plan view, the peak of the roof was moved forward to contact the picture plane and then a measuring line dropped vertically from this point. From the elevation, the true height of the peak was projected to this measuring line and a receding line drawn from this point in the perspective drawing to the right vanishing point. Then the outlines of the roof were drawn. The peak of the dormer was located in the same manner and the dormer drawn. Next the right edge of the cottage was moved forward to the picture plane and a measuring line drawn from this point to intersect the line from the elevation. The true heights of the wall, door, and windows were marked on this line, and the receding lines from these marks to the vanishing points drawn to locate these features in the perspective drawing.

Figure 4-160.—Working sketch on cross-section paper.

PERSPECTIVE IN ILLUSTRATING

The perspective projection techniques described in this chapter are those which are generally used by the architectural draftsman. The illustrator customarily takes some liberties with the procedures presented here. The illustrator's approach to perspective drawing is presented in chapter 14.

Figure 4-161.—Sketching circles.

WORKING SKETCHES

Freehand sketches are sometimes used as the basis for making a machine part or some other object, particularly at advanced bases or aboard ship. Often a drawing is needed so quickly that there is no time for a finished drawing to be prepared. These sketches may be made from actual machinery or from structures at the scene of a construction job. As a draftsman you should know how to make a working sketch.

Figure 4-162.—Sketching curves.

Materials

To make a freehand sketch, you need paper, pencil, and eraser. A 2H pencil may be used or a common No. 2 pencil. Cross-section paper like that used in making graphs or charts is helpful. You can assign a value to a square, so that it is easier to draw your sketch to scale. (See fig. 4-160.)

Technique of Sketching

In freehand pencil sketching, draw lines with a series of short strokes, instead of trying to draw each line with one stroke. Using short strokes, you can better control the direction of your line and the pressure of your pencil on the paper.

Figure 4-163.—Using a pencil and string as a substitute for a compass.

Figure 4-164.—The use of construction lines in sketching an object.

In sketching lines, swing your hand in the direction your line should go and back again a couple of times before you touch your pencil to the paper. In this way, you get the feel of the line. In sketching long lines, place a dot where you want the line to begin and one where you want it to end. Then use these dots to guide your eye and your hand as you draw the line.

Keep your freehand sketch neat. To do this, sketch your lines lightly first. Lines which are not essential to the drawing can be sketched so lightly that it is not necessary to erase them. Essential lines can be darkened by running the pencil over them with more pressure after they have been drawn lightly first.

Perfectly round circles are one of the most difficult things to draw freehand. Figure 4-161 shows methods of drawing circles and curves using straight lines as construction lines. First draw two straight lines crossing each other at right angles, as in figure 4-161A. The point where they cross will serve as the center of the circle. The four lines radiating from this center will serve as the radii of the circle. You can use a piece of marked scrap paper to measure an equal distance on each radius from the center. Sketch a square, with the center of each side passing through the mark defining a radius. (See fig. 4-161B.) Now sketch in your circle, using the angles of the square as a guide for each arc.

In figures 4-161C and 4-161D, four lines, instead of two, are sketched crossing each other. The radii are measured as in constructing the other circle, but the square is not added before the circle is drawn.

Figure 4-162 shows a convenient way of sketching arcs, tangent arcs, and curves by blocking them in with straight lines.

You can make a substitute for a compass with a pencil, a piece of string, and a thumbtack. Tie one end of the string to your pencil near the tip. Measure the radius of the circle you are drawing on the string, and insert your tack at this point. Then push the tack in hard at the center of the circle. Now swing your pencil in a circle, taking care to keep it vertical to the paper. (See fig. 4-163.)

Figure 4-165.—Progress of a working sketch.

Construction Lines

When you are drawing a part, such as that shown in figure 4-164, don't start at one corner and draw it detail by detail and expect it to come out with the various elements in correct proportion. It is better to block in the over-all shape of the object first. (See fig. 4-164a.) Then draw light guide lines at the correct angle for the various outlines of the object. (See fig. 4-164b and c.)

Finish the sketch, by first making an outline of the object, and then drawing in the details, as shown in figure 4-164d.

Order of Working

If you are assigned to make a working sketch from a machine part or a model, first choose a clean sheet of paper, either plain or ruled. Estimate the size the sketch should be, and select the views which will give the best picture of the object. Then draw the orthographic projections of these views, leaving adequate space between them for dimensions.

When you draw the views:

1. Sketch in center lines, as shown in figure 4-165A.
2. Block in the views.
3. Sketch in the outlines, aligning them as in figure 4-165B.
4. Draw the details on the surface of the views.
5. Darken the lines of the finished drawing.
6. Use an artgum or a kneaded eraser to erase the construction lines which are no longer needed.
7. Draw all necessary extension and dimension lines.
8. Letter in the dimensions. (See fig. 4-165C.)

CHAPTER 5

DEVELOPMENT OF SURFACES

A surface has two dimensions—length and width. It is bounded by lines which are either straight or curved. The surface itself may be plane, plane-curved as the peripheral surface of a cylinder, warped as the surface of a screw thread, or double curved as the surface of a sphere. A plane surface is flat. A plane curved surface can be unrolled and laid out flat; a three-dimensional figure made up of plane surfaces can be unfolded as shown in figure 5-1. This unfolding or unrolling is called developing the surface. A warped surface or a double-curved surface cannot be developed except approximately. The term development is applied to the procedure for constructing the unfolded figure, to drawings as a whole which include the views necessary to construct the unfolded figure, and more specifically to the view which represents the unfolded figure. This latter view is also called a stretchout.

In figure 5-2, a number of three-dimensional figures are illustrated. Try to form a mental picture of what would happen if the surfaces of these figures were unfolded or unrolled and laid out in a flat plane. The polyhedrons, of course, would be merely a system of connected squares, triangles, or other polygons. A cylinder with parallel ends would unroll into a parallelogram. A cone would unroll into a section of a circle. However, warped surfaces could not be made to lie flat, and double-curved surfaces present a similar problem.

USES OF DEVELOPMENTS

In the Navy, developments are used for many types of sheetmetal work, such as ducts for heating, ventilating, and air conditioning systems. Also for flashing, valleys, gutters, and downspouts for buildings. Developments are used for the fabrication of parts for boats, ships, and airplanes, and structural features involving the use of sheetmetal or metal plates. Even though the metal sheets used for some of this work are thicker and heavier than the material usually used in a sheetmetal shop, the same principles are applied in constructing the developments.

In the usual sheetmetal fabrication shop, the required shapes may be formed by rolling, folding, and crimping. However, warped and double-curved surfaces can be produced in sheetmetal only through the application of pressure in such a way as to cause a flow of metal sufficient for the shape to be retained after the pressure is released. For example, automobile fenders and body sections are made in this way. Concentric articles, like metal bowls, can be spun from flat sheetmetal on a lathe. Pressure is applied with tools made for the purpose while the metal is spinning.

Figure 5-1.—A rectangular pan.

Figure 5-2.—Three-dimensional shapes.

Figure 5-3.—What happens at a bend.

A development may be drawn directly on the metal or a paper pattern may be made. For repeated usage, a template may be made from the drawing. To withstand the wear and tear of shop use, templates are usually made of sheet steel.

BENDS AND SEAMS

The developments worked out in this chapter do not include allowances for bends or seams, because these vary according to the material used and its thickness. Considerable knowledge of shop work is necessary in order to allow for bends and to choose the best type of seam for any particular piece and in order to cut the development out of the metal without errors and waste. Note that most of the developments in this chapter provide for the seam to fall on the shortest side when there is a choice. When a number of pieces of similar shape are to be cut from one sheet of metal, the seam may be alternated from side to side in order for the pieces to fit together without much waste metal between them.

Bend allowance is the amount of material consumed in making the bend. The bend allowance is affected by the shrinking and stretching of the metal at the bend. This varies with the differend bend radii, the thickness of the metal used, the type of metal, and its temper. Metallurgists have developed methods for determining the bend allowance and have found, by actual bending, the effect of the factors just mentioned. When metal is bent, the outside of the bend is stretched or lengthened, while the material on the inside is forced to shrink or shorten as shown in figure 5-3. When the sheet is being bent, the metal along a line through the middle of the thickness of the sheet is a neutral zone, where neither shrinking or stretching occurs, but retains the same length. It is along this neutral axis that bend allowance is computed.

Illustrated in figure 5-4 are some of the more common joints, seams, finished edges, and connectors used in sheetmetal work.

The place where two sheets of metal are joined together is called a seam. The three most common types of seams used in sheetmetal work are the lap, grooved, and the standing seam.

The lap seam is the least difficult to fabricate. In making this seam, the pieces of stock are merely lapped one over the other as shown in figure 5-5A, and secured either by riveting, soldering, spot welding, or by all three methods, depending on the nature of the job.

A grooved seam is used in the construction of cylindrical objects, such as funnels, pipe section, containers, and so on. The steps in forming a grooved seam are shown in figure 5-5B.

Figure 5-4.—Some common sheetmetal joints, seams, finished edges, and connectors.

Figure 5-5.—Lap, groove, and standing seams.

The standing seam is frequently used when joining two sections or parts of an object, such as the splash ring to the body of a funnel. The steps in making a standing seam are shown in figure 5-5C.

If allowances must be made for bends, and seams must be shown on the developments which you draw, you should obtain the necessary data from the designers or the shops if they failed to give you these requirements at the outset.

METHODS OF DEVELOPMENT

The three principal methods of developing the surface of three-dimensional objects are called parallel development, radial development, and triangulation. Parallel development is used for surfaces such as those of prisms or cylinders. (See fig. 5-6A.) Radial development is used for surfaces such as those of cones and pyramids, which may be said to be generated by a line of which one end remains fixed while the other end rotates about it. (See fig. 5-6B.) Triangulation is used for surfaces which do not lend themselves to either of the other two methods and to approximate the development of warped surfaces. (See fig. 5-6C.)

Figure 5-6.—A. Parallel development. B. Radial development. C. Development by triangulation.

Figure 5-7.–Development of double-curved surfaces.

Figure 5-9.—Development of a truncated hexagonal prism.

power conversion, since it is able to link the two forms of energy. Reacting initially to the input or static conditions, it takes energy from the input and transports it to another part of the device. Here the energy can be drawn upon to create an output or to amplify microwave signals.

Two elements which require further explanation have been introduced: the path of the electron from its source to its final destination, and the "other part of the device" where the energy of the electron is finally utilized. Each will be considered in turn; then the combining of the two elements to form a working microwave tube will be discussed.

The Electron Path

The path of the electron can best be understood by considering the forces acting upon it. Refer to figure 12-18 (A). The source of all electrons is the cathode. Properly designed and located, the cathode supplies a unidirectional stream of electrons. Immediately after the electrons are emitted, the combined action of magnetic and specially shaped electric fields forms them into a beam.

After the beam is formed, all of the component electrons travel at approximately the same velocity. The negatively charged electrons are injected into an electric field which is perpendicular to their forward motion. (This field arises from voltages applied between opposed elements, the anode and the sole, and in the absence of other forces a given electron would soon be "collected" by the positive element, the anode.)

However, a second force acting upon the electron arises from its forward motion through a magnetic field oriented crosswise to both the electron path and the previously described electric field; hence, the term "crossed field" tube. By the conventional rule for this situation, the resultant force on the electrons is opposite to the force of the electric field.

Appropriate adjustment of the fields results in a controlled beam path which is circular and terminates at an element called a collector.

To summarize, the electron beam is formed at the electron gun (cathode), follows a circular path between the anode and the sole, and terminates at the collector.

When the forces acting on the beam are expressed in standard electrical terms and equated for the controlled beam condition, the electrical force equals the magnetic force. Therefore, electron or beam velocity is equal to the ratio of electric field strength (E) to magnetic field strength (B). For the practical situation, B is constant and is supplied by a permanent magnet integral with the tube. Thus, beam velocity is directly related to E, the field strength between sole and anode. In more practical terms, E is given by the potential difference between the anode and the sole, divided by the distance between them (which is fixed). Therefore, beam velocity is linearly controlled by variation of either the anode voltage or the sole voltage.

The Delay Line (Anode)

The next step in understanding the basic principles of the crossed field device is to consider the part of the device where the electron beam develops microwave energy.

The sole serves as little more than one of the electrodes for the static electric field, as discussed in the previous section. The anode, however, is a much more complex component than has been suggested. The anode in many crossed field tubes is of such a form that it is called an INTERDIGITAL DELAY LINE.

The interdigital delay line is best described as a normal waveguide transmission medium in which opposing walls have been extended towards one another in alternately spaced fingers or digits, as shown in figure 12-19. The velocity of wave travel in the resulting interdigital structure is decreased, because of the longer path along its boundaries. In effect, such a

Figure 12-19. —Interdigital delay line compared with a normal waveguide.

Double-curved surfaces, such as the surface of a sphere, may be developed approximately by several methods which you will probably never have occasion to use in the Navy but which are interesting in that the identical methods are applied in various map projections. See chapter 12 of Blueprint Reading and Sketching, NavPers 10077-B for elementary information on map projections. A sphere may be cut into horizontal sections, or zones, which may be considered, and developed, as frustums of cones, as shown in figure 5-7A. A sphere may also be cut into equal meridian sections, called lunes, and these developed as if they were sections of cylinders. (See fig. 5-7B.)

PARALLEL DEVELOPMENT

The surfaces of prisms and cylinders are made up of parallel elements or of elements that can be treated as parallel elements. For example, in figure 5-8, the steps in developing a rectangular prism are illustrated.

1. In order to determine the length of all the edges of the prism, draw the front and top views in orthographic projection. (See fig. 5-8A.)
2. Draw the development to one side of the front view so that the dimensions of vertical elements on that view can be projected to the development as shown in figure 5-8B.
3. Transfer the dimensions of other elements from the top view. (See fig. 5-8C.) Notice that all bend lines are marked with crosses near their ends to distinguish them from outlines.
4. To check the drawing, measure the lines of edges which are to be joined as illustrated in the pictorial drawing in figure 5-8D. Such edges must correspond exactly.

In figure 5-9, the steps in the development of a truncated hexagonal prism are illustrated.

1. Draw a front view and a bottom view of the prism in orthographic projection. (See fig. 5-9A.)
2. Since the true shape of the slanting plane and the length of the lines of its edges are not shown in these views, draw an auxiliary view as shown in figure 5-9B. Note that it is not necessary to draw the entire prism in the auxiliary view, since only the dimensions of the plane surface are required.
3. Project the lines of the front view horizontally as the first step in constructing the development. (See fig. 5-9C.)
4. Number the points of intersection of planes on the bottom view, and mark off line segments of the same length on the base line of the development.
5. Erect vertical lines from these numbered points to intersect the lines projected from the front view of the prism. (See fig. 5-9D.) These intersections mark the corners of the prism.
6. Connect the intersection points with straight lines.
7. To complete the development of a closed three-dimensional figure, draw the bottom of the prism attached to one of the sides at the base line. Draw the slanting plane at the top of the prism, as it is shown in the auxiliary view, attached to one of the sides. (See fig. 5-9E.)
8. Check all measurements of edges to be joined as shown in the pictorial drawing in figure 5-9F, in order to be sure that they will coincide exactly.

The development of a truncated cylinder, illustrated in figure 5-10, follows a very similar procedure. The cylinder is considered to be a prism with an infinite number of sides. In developing a cylinder, the number of sides must necessarily be limited, but the greater the number of sides, the more accurate the development will be.

1. To develop one-half of a two-piece elbow, first draw a front and bottom view of that piece in orthographic projection. (See fig. 5-10A.) Since the elbow does not require an end piece, it is not necessary to draw an auxiliary view showing the true shape of the ellipse formed by cutting plane at the top of the cylinder.
2. Divide half of the circumference of the circle into a number of equal parts (fig. 5-10A.) The parts should be small enough so that, when a straight line is drawn between division points, it will approximate the length of the arc. Project lines from these points to the front view, as shown in figure 5-10B. The resulting parallel lines on the front view are called elements.
3. Lay off the base line, called the stretchout line, of the development. The length of this line may be calculated as π times the diameter of the cylinder (3.1416 x D).
4. Divide the stretchout line into twice the number of equal parts as the number on the half circle of the orthographic view. (See fig. 5-10C)
5. Erect perpendiculars at each point, as shown in figure 5-10C.
6. As shown in figure 5-10D, project lines horizontally onto the stretchout from the points

Figure 5-10.–Development of a truncated cyclinder.

of intersection of the elements with the top of the cylinder.

7. Using a curve, join the resulting points of intersection in a smooth curve. With points numbered around the bottom view as shown in figure 5-10D, corresponding points are located on the top of the cylinder as shown in the front view—point 13 is behind point 1. With the stretchout to be rolled up toward the viewer, the corresponding points are located as shown in the developed view.

When the two pieces of the elbow are identical, it is only necessary to make one pattern.

When a four-piece elbow is to be drawn, the same steps are followed to produce as many developments as may be required. The orthographic view may be drawn of the whole elbow and the developments drawn beside each separate piece, as illustrated in figure 5-11. Here only one end and one middle development are drawn, since the other two pieces are identical with these.

INTERSECTIONS

When two pieces, such as two cylinders or a cylinder and a prism, intersect, it is necessary to determine the exact points of intersection in order to make developments for the pieces that will fit together without gaps or unnecessary overlaps. These intersections are determined by carefully drawing the elements intersecting on orthographic views and then projecting or transferring these intersection points to the developments. In figure 5-12, for example, the steps in making developments for a T-joint are illustrated. The T-joint consists of two cylinders with equal diameters which intersect at right angles.

1. As shown in figure 5-12A, draw a front view and a side view of the T-joint. A bottom view representing the open end of the other cylinder might also be drawn. However, since this cylinder is circular and therefore symmetrical, a semicircle may be drawn attached

Figure. 5-11.—Developments for a four-piece elbow.

9952

Figure 5-12.—Development of a T-joint composed of cylinders of equal diameter.

Figure 5-13.—Development of a T-joint with two cylindrical pipes of unequal diameter.

to the front view and the division points for the elements located on it. Also divide the through pipe in the side view into equal segments. The points are numbered (fig. 5-12A) for purposes of explanation in the following paragraphs.

2. As shown in figure 5-12B, draw the elements on both cylinders. The points where the elements of one cylinder intersect those of the other define the intersection of the two cylinders. In the side view point 7' is behind point 7' and point 3' is behind point 3. In the front view points 7' and 7 are on the near side and points 3' and 3 are on the far side.

3. As shown in figure 5-12C, draw the surface pattern of the branch pipe at one side of the orthographic view so that the length of each element can be projected from the front view. As in the last example, the length of the stretchout is equal to $\pi \times D$ and the number of divisions is equal to twice the number of segments into which the semicircle was divided. With a stretchout to be rolled up toward the viewer, points 3, 3', 7', and 7 are located on the top of the branch pipe as shown.

4. As shown in figure 5-12D, draw the surface pattern of the through pipe below the front view. Again, the length of the stretchout is π D. The number of divisions is equal to the number of segments into which the circle was divided. Project lines down from the branch pipe to locate the opening for it. Points 5 and 5' are along the centerline of the stretchout; points 1 and 9 extend halfway up the through pipe—therefore they are at quarter points on the development. Points 3, 3', 7, and 7' occupy corresponding positions as shown in the three views.

Unequal Diameters

When the T-joint is made of two cylindrical pipes of unequal diameter, the procedure differs slightly.

1. Draw the orthographic views.

2. Divide the smaller diameter branch pipe into equal parts, and draw the elements on this pipe in both views, as shown in figure 5-13A. The length of each element is shown in the side view.

3. Project lines from the upper end of each element in the side view to the front view, as shown in figure 5-13B. The intersections of these lines with the vertical lines drawn on the branch pipe define the intersection of the two pipes.

4. Draw the line of intersection on the front view

5. As shown in figure 5-13C, draw the surface pattern of the branch pipe to the left, continuing the projection lines from the other views. As in previous examples, the stretchout length is π D and the number of divisions is twice those of the semicircle.

6. As shown in figure 5-13D, draw the development of the through pipe below the front view. Project lines down from the branch pipe; the points marking the opening will fall on these lines. As before, the length of the stretchout is π times the diameter of the through pipe; but the pattern is not, in this case, marked off into equal divisions. By measurement locate the centerline of the stretchout. Then, on both sides of the centerline, lay off the distances picked off the side view of the through pipe; for example, lengths a and b in the illustration. Note that these distances are not the horizontal intervals between elements of the branch pipe; they are chords of the arcs of the big circle which are intercepted by the elements of the smaller cylinder.

Acute Angle Intersection

Figure 5-14 illustrates the steps in drawing a round pipe joint made up of two cylindrical pipes of unequal diameter which intersect at an angle other than 90 degrees.

1. Draw the front and top orthographic views (fig. 5-14A.) The ellipse formed by the top of the branch pipe may be omitted at this point and drawn later.

2. Divide the two semicircles shown in figure 5-14B and draw the elements on the branch pipe in both views.

3. Project lines down from the left end of each element in the top view to the corresponding element in the front view, and draw the line of intersection (See fig. 5-14C.)

4. Draw the ellipse formed by the end of the branch pipe in the top view, by projecting lines up from the upper end of each element in the front view to the corresponding element in the top view. (See fig. 5-14D.)

5. Draw the pattern of the branch pipe to the right and perpendicular to the pipe as it appears in the front view, as shown in figure 5-14E. The length of the stretchout is π D; it is divided into 16 equal parts because the semicircle was divided into eight parts.

9955

Figure 5-14.—Development of a round pipe joint made of two cylindrical pipes of unequal diameter intersecting at an angle other than 90 degrees.

Figure 5-15.—Development of a pipe joint in which a rectangular pipe intersects a round pipe at an angle other than 90 degrees.

6. Draw the pattern for the main pipe to the left, with lines projecting from the intersection of the two pipes on the orthographic view to locate the opening for the branch pipe. (See fig. 5-14F.) The length of the stretchout is π times the diameter of the larger, vertical, pipe. The divisions laid off on either side of the centerline (e to d, d to c, etc.) are the distances along the arc of the larger circle which are created by the intersection of the elements of the smaller circle.

Rectangular and Round Pipes

When a pipe joint consists of a rectangular pipe intersecting a round pipe at an angle other than 90 degrees, the procedure is similar.

1. Draw the orthographic views, as shown in figure 5-15A, dividing the upper surface of the rectangular pipe in the top view by equally spaced elements.
2. The points of intersection of these lines with the circle are then projected down to the upper and lower surfaces of the branch pipe in the front view. (See fig. 5-15B)
3. Develop the surface pattern of the rectangular pipe perpendicular to it in the front view, as shown in figure 5-15C
4. Draw the surface pattern of the round pipe, with the opening for the rectangular pipe, to the side of the front view, as shown in figure 5-15D. The distances a to b to c to d are the lengths of arc intercepted by the elements of the rectangular pipe.

RADIAL DEVELOPMENT

The sides of a pyramid and the elements of a cone meet at a point called the vertex or apex. These same lines meet at a point in the development of a pyramid or cone and are said to radiate from this point. Consequently, the method of developing pyramids or cones is called radial development.

In radial development, the same general procedures are followed as those used in parallel development, except that since the slanting lines of pyramids and cones do not always appear in their true lengths on the orthographic views, certain other procedures must be followed in order to determine these true lengths. To find the true lengths of these edges, the pyramid may be rotated so that some of the edges appear in their true lengths in the views, as shown in figure 5-16B. In this case, the lines which appear as horizontal lines in the top view are shown in outline and in their true-length in the front view. In other words, when a line appears as horizontal or as a point in the top view, the corresponding line in the front view is its true length. Conversely, when a line appears as horizontal in the front view, the corresponding line in the top view is its true length.

Usually, instead of rotating the whole pyramid, the line of the edge itself may be simply rotated into the horizontal on a conventional orthographic view. For example, in figure 5-16C, the line of an edge from apex to base as it appears in the top view is used as the radius

Figure 5-16.–Methods of finding the true length of a line in radial development.

9958

for an arc to the horizontal. The point of intersection of the arc with the horizontal is projected to the front view and a true-length line for that edge drawn, as shown in figure 5-16D.

The steps for developing a truncated pyramid are illustrated in figure 5-17. This is a trasition piece for connecting a large square pipe with a smaller one. Normally the square ends would be terminated in square collars which would also be developed.

1. Draw the orthographic views, completing the lines of the sides to the apex.

2. Rotate the line of one edge in the top view to the horizontal and project it to the front view. (see fig. 5-17B.).

3. Draw an arc with a radius equal to the length of this true-length line plus its extension to the apex of the pyramid, and a second arc defining the upper limit of the true-length line, as shown in figure 5-17C.

4. Step off lengths along these arcs equal to the sides of the pyramid. (See fig. 5-17D.)

5. Connect these points successively with each other and also connect them by light lines with the vertex, as shown in figure 5-17D. Heavy up the portions of these rays which are the sides of the pyramid and mark them as bend lines.

PENTAGONAL PYRAMID

To develop a truncated pentagonal pyramid like that shown in figure 5-18, the same general steps are followed. However, since one lateral edge appears in its true length in the front view, the limits of the other edges may be projected

Figure 5-17.—Development of a truncated pyramid.

structure develops a series of space harmonics whose summation is seen as microwave energy propagated at the delayed or reduced rate.

(One type of magnetron, called the INTERDIGITAL MAGNETRON, uses the interdigital transmission line as the interaction space in the generation of RF power. The action of that device is more or less a combination of the conventional magnetron and the backward wave oscillator.)

A particular delay line can be designed for either forward wave or backward wave propagation. The distinction between the two arises from comparison of the direction of the dominant space harmonic with the direction of the energy which sustains it.

The amount of delay is established by adjusting various dimensions within the line. As with the more familiar waveguide, the delay line is a broadband device capable of transmission over a considerable frequency range. Its physical shape is a matter of convenience and, in this case, it is circular.

Production of the space harmonics is the same as in any oscillator, starting with noise and leading to generation of usable frequencies. These frequencies are determined by the fields of the device in a manner similar to the action of a magnetron.

In brief, the electrons serve as a link between the externally applied input energy and the microwave output energy. The electrons determine, by their velocity, the output frequency in an oscillator (and the optimum frequency for an amplifier). At the same time, they determine by their quantity (beam current magnitude) the power output level.

In contrast with magnetrons, the use of a beam in crossed field tubes eliminates cathode back bombardment, thus increasing emission life. In comparison with linear beam devices such as a traveling wave tube, where beam velocity (and therefore tube frequency) are functions of the square root of the tuning voltage. BWO's provide a very nearly linear relationship between tuning voltage and tube frequency.

Interaction

As the electron beam travels in a circular path between the sole and the anode (delay line), electrons of the beam pass near the fringe fields of the noise generated space harmonic waves on the delay line. For electrons of a given velocity, as determined by the externally applied delay line voltage, space harmonics of synchronous phase velocity result. Whether these are forward or backward waves is determined by the design of the delay line. In either case, since phase velocity of space harmonic waves is, in general, a function of frequency, it is the velocity of the electrons that determines the operating frequency.

The total field in this case is a combination of the externally applied fields and the internally developed space harmonic field. By following the laws governing electron motion in crossed electric and magnetic fields, electrons drift in a direction perpendicular to the space harmonic fields. This drift is such that they congregate in bunches, one bunch per space harmonic wavelength.

In the bunches, electrons work their way across from the original beam position to the slow wave structure (delay line), staying locked in synchronism as they do so. Their direction of motion is such that they give up to the RF field the energy acquired from the d-c source, thus causing the space harmonic wave to grow.

PHYSICAL AND ELECTRICAL CHARACTERISTICS

The basic elements of the M-BWO together with the usual polarities of applied d-c voltages, are indicated in figure 12-20. The arrangement of the basic elements can be separated into three regions as follows:

1. The gun region, including the cathode, grid, and accelerator.
2. The interaction space, including the delay line and the sole.
3. The collector element and the sole.

In practical tubes, the collector and the delay line are integral parts of the tube body and are maintained at ground potential. An exception is that the "beam miser" (to be discussed later in this chapter) places the collector at cathode potential.

The electron gun comprises a heater, cathode, control grid, and accelerator anode. The control grid is operated at zero potential or slightly negative with respect to the cathode. The accelerator electrode is maintained at a positive potential with respect to the cathode. The sole electrode is negative with respect to the cathode, and the delay line (commonly referred to as an anode) is positive with respect to the cathode.

993

Figure 5-18.–Development of a truncated pentagonal pyramid with the upper corners cut by a slanting plane.

Figure 5-19.–Development of an offset transition piece.

onto the line of this edge in order to determine the true lengths.

1. Swing arc oa.
2. Step off the five distances aa and draw rays from points a to o.
3. Transfer distances ab, ac, and ad (or ob, oc, and od) from the front view to the stretchout.
4. Connect bcddcb.
5. Heavy up the pattern lines and mark the bend lines.

OFFSET TRANSITION

Figure 5-19 shows the development of an offset transition piece. It is called offset because the center of one end is not in line with that of the other end. The three parts consist of an upper section and a lower section, which are truncated rectangular prisms, and a third section, which is a truncated oblique pyramid.

1. Draw the orthographic views, extending the lines of the sides of the pyramid to its apex in both views.
2. Rotate the lines of the sides to the horizontal in the top view, project the points thus located to the front view, and draw the true-length line. (See fig. 5-19B.)
3. At one side of the views, develop the surface pattern of the oblique square pyramid as shown in figure 5-19C. The development consists of four triangles which are constructed one at a time using the lengths of the sides from the other views. For example, construct triangle oab using ab from the top view and oa and ob from the front view. In a similar manner, construct triangles boc, cod, and doa.
4. Plot e, f, g, h, and e from the lengths in the side view. For example, transfer ae and bf (or oe and of) to the development to establish ef.
5. Draw the surface patterns of the upper and lower prisms, as shown in figure 5-19D.

CONE

The development of a cone is similar. It is considered to be a pyramid with an infinite number of sides. In practice, of course, the number of sides must be limited. Elements representing these sides are drawn on the orthographic views and projected to the development.

Figure 5-20.—Development of a truncated right cone.

144 OF 327

ED

056 238

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

The steps in developing a truncated right cone are illustrated in figure 5-20.

The right cone has a centerline which is perpendicular to its base. Thus the elements on a right cone are all the same length. The true length of these elements is shown by those which fall to the extreme right and left in the front view, since these elements are horizontal lines in the top view. The cone in figure 5-20 is cut by a slanting plane. Therefore the termination points of the elements between the two outside elements must be projected to one of the outside lines in order for their true length to be determined.

1. Draw the orthographic views, including either a side view, as shown in figure 5-20A, or an auxiliary view of the ellipse which is formed by the slanting plane. Note that the center of the ellipse must be determined since it does not fall on the centerline of the cone. This center point is projected to the side view and defines the length of the minor axis (length B in 5-20C) of the ellipse. The length of the major axis (length A in 5-20C) is defined by the length of the slanting line in the front view.

2. Develop the surface pattern of the cone (fig. 5-20B), using the length oa from the apex to the base as a radius for drawing the arc. Step off on this line the equally spaced divisions of the base. The angle aoc, the total arc ac, and the arc length of each division may be computed for use in constructing or checking the development. For example, let ab = 5.5 in. and let oa = 9.0 in. Arc ac is equal to the circumference of the base of the cone; therefore arc ac = π x diameter = π x 5.5 in. = 17.28 in. Since there are 24 divisions along arc ac, each division equals 17.28 in. ÷ 24 = 0.72 in. Angle aoc is part of a whole circle for which the circumference is 2π x radius = 2π x 9.0 = 18.0π. Angle aoc relates to 360° in the same ratio that arc ac relates to the whole circle:

$$\frac{\text{angle aoc}}{360^\circ} = \frac{\text{arc ac}}{\text{whole circle}} = \frac{5.5\pi}{18.0\pi} = \frac{5.5}{18.0} = 0.036$$

angle aoc = 360° x 0.306 = 110°

3. Measure each element individually (the true length as projected on line ob) and transfer this measurement to the development. The ends of each of these elements define the curve of the upper edge of the peripheral surface. (See fig. 5-20B.)

4. To complete the development of a solid figure, draw the circle of the surface of the base and the ellipse of the top surface attached to the peripheral surface as shown in figure 5-20C.

TRUNCATED INVERTED CONE

In figure 5-21, the pouring lip on the round measure is a truncated portion of an inverted cone. The lower end is cut by a plane parallel to the base and the upper end is cut by a slanting plane. The same procedures may be used to find the elements on this lip as those described in connection with the truncated cone shown in figure 5-21. However, a shorter method may also be used to develop the surface pattern of the lip.

Figure 5-21.—Development of a pouring lip.

Figure 5-22.—Triangulation development of a transition piece.

1. Draw an orthographic view, and locate the apex of the inverted cone (o in fig. 5-21A).

2. Draw a semicircle (radius ba) attached to the lower edge of the pouring lip, and divide this into equal spaces; 12 divisions are used in the illustration.

3. As the first step in developing the surface pattern, draw an arc with a radius oa equal to the line from the apex o of the angle to the lower edge of the lip a along one of the true-length lines (See fig. 5-21A.)

4. Draw a centerline through this arc, and step off the same number of equal spaces on each side of this line as appear on the semicircle in the front view (12 divisions in the example).

5. From the final steps on each side, draw lines the distance of the short side de of the lip, as shown in figure 5-21B and C, and also locate a point c beyond the arc on the centerline at a distance equal to the long side ac of the lip in the orthographic view.

6. Draw a line from this point c to the outer edge of the lip e at the seam as shown in figure 5-21C.

7. Bisect this line ce, and draw a line fg perpendicular to ce which intersects the centerline at point g.

8. With this intersection g as the center and with a radius gc equal to the distance from this center to the points c and e already located on the outer edge of the lip, draw an arc describing this outer edge. (See fig. 5-21D.)

TRIANGULATION

Triangulation is slower and more difficult than parallel line or radial development, but it is more practical for many types of figures. Also it is the only method by which the developments of warped surfaces may be approximated. In development by triangulation, the piece is divided into a series of triangles as in radial development. However, there is no one single apex for the triangles. The problem, therefore becomes one of finding the true lengths of the varying oblique lines. This is usually done by drawing a true-length diagram.

Figure 5-22 illustrates the steps in the triangulation of a warped transition piece joining a large square pipe and a smaller round pipe.

1. Draw the top and front orthographic views (fig 5-22A).

2. Divide the circle in the top view into a number of equal spaces and connect the division points with the corners of the square, as shown in the top view in figure 5-22B.

3. Transfer the division points down to the front view, and draw the elements from the numbered points to corners A and B as shown in figure 5-22C.

4. Now the true length of each of these elements may be found by drawing a right triangle (A33 in fig. 5-22C, for example) with a base (3A) equal to the length of an element (3A) on the top view and with an altitude (33) equal to the altitude of the corresponding element on the front view. The hypotenuse (3A) of the triangle is the true length of the element. In figure 5-22C, the true-length diagram consists of only three right triangles. Since the piece is symmetrical, a number of the elements are the same length.

5. To draw the surface pattern, construct one triangle at a time; for example, triangle A21 in figure 5-22E. Draw line A1 using the length from the true length diagram in 5-22D. From point A, swing an arc of radius length A2 taken from the true length diagram. From point 1 swing an arc of radius length 12 taken from the top view of figure 5-22D. The intersection of the arcs establishes point 2 and completes triangle A21.

6. Using lengths from 5-22D, build triangles A23, A34, and A45 onto triangle A21.

7. To set point D in the development, swing length D5 (which is the same length as A5) from point 5 and swing length AD (taken from the top view of 5-22D) from point A. This completes one-fourth of the development; since the piece is symmetrical, the remainder of the development may be constructed using the lengths from the first part.

8. It is difficult to keep the entire development perfectly symmetrical when it is built up from small triangles. Therefore, you may check the overall symmetry by constructing perpendicular bisectors of AB, BC, CD, and DA (fig. 5-22E) and establish point O. From point O swing arcs a and b. Arc a should pass through the numbered points and arc b should pass through the lettered points. Further, the length of arc a should be equal to π times the diameter of the circular opening in the top of the transition piece.

RECTANGULAR TRANSITION

Figure 5-23 shows the steps in developing a rectangular transition piece which is not true pyramid because the extended lateral edges

9964.

Figure 5-23.—Development of a rectangular transition piece which is not a true pyramid.

would not meet at a common vertex. This may best be developed by drawing diagonals which split the sides into two triangles. These diagonals are usually drawn as dotted lines to differentiate them from other elements. Then the true length of each element is found, and the surface pattern developed by constructing each triangle in turn. To find the true-length lines, a true-length diagram is drawn.

1. As shown in figure 5-23A, draw the orthographic views and the diagonals.

2. Draw the true-length diagram as shown in figure 5-23B. The altitude of the triangles in the diagram is the height of the piece. The base A1 of triangle A11 is length A1 taken from the top view; the hypotenuse A1 is the true length. Similarly, length B1 from the top view is the base of triangle B11; hypotenuse B1 is the true length.

3. Construct the development (fig. 5-23C) one triangle at a time. For example, construct triangle A1B using true lengths A1 and B1 from the diagram and length AB from the top view. To add triangle 1B2, use length 12 from the top view and length B2 from the true-length diagram. Build the remaining triangles onto these in similar fashion.

WARPED TRANSITION

The fitting in figure 5-24 has a warped surface. Its base is round and its top is oblong.

Figure 5-24.—Development of a warped transition piece.

The method for development consists of dividing the surface into quadrilaterals of approximately the same size, and then drawing a diagonal across each of these to produce two triangles. When the true lengths of these elements have been found, the surface pattern may be drawn, triangle by triangle.

1. Draw the front and top orthographic views as shown in figure 5-24A.

2. As shown in figure 5-24B, divide the circle of the base into equal parts (six divisions of the semicircle are shown). Divide the arcs on the oblong into equal divisions (three on each quarter-circle are shown).

3. Project the division points to the front view and draw the elements in both views. Draw diagonals using dashed lines.

4. Draw a true-length diagram as shown in figure 5-24C and D. The altitude of the true-length triangles is the height of the transition piece. The first small triangle on the right of the diagram has a base G8 the length of which is taken from the top view as indicated in 5-24C; the hypotenuse G8 is the true length. Another example is the bold triangle FG8 in 5-24C: the base FG is taken from the top view; the hypotenuse F8 is the true length. In the bold triangle in 5-24D, the base F7 is taken from the top view; again, the hypotenuse F7 is the true length.

5. Construct the development (fig. 5-24D) a triangle at a time. For triangle 8FG, the lengths G8 and F8 are taken from the true-length diagram and FG is taken from the top view. For the next triangle, length F7 is taken from the true-length diagram and length 78 from the top view. The entire development is constructed by building the triangles one upon another in similar fashion.

CHAPTER 6

MACHINE AND STRUCTURAL DRAWINGS

As an Illustrator Draftsman, you may be assigned to a repair ship or a tender. Most of the drawings with which you will be concerned will be adaptations of existing drawings. You will have access to prints of manufacturers' drawings and BuShips drawings. However, when a part is broken, it may be necessary to make a drawing so that the part may be rebuilt. Also, various minor modifications or repairs to structures or machinery may require that drawings be prepared locally. The draftsman making detail or assembly drawings should know something about materials and the different terms used in connection with them. He should also have an acquaintance with shop work and the fabrication of metal and plastic products. He should be familiar with the nomenclature of ships and aircraft so that he can relate the various drawings to the appropriate portion of the structure.

MACHINE DRAWINGS

When a complex piece of machinery is to be made, whether it will be produced as a single unit or in quantity, the problems involved in producing it are worked out on the drawing board. First, a design drawing is made by an engineer, engineer officer, or a well-trained and experienced draftsman working from sketches made by an engineer. Then detail drawings of each part are made from this design drawing. Finally, an assembly drawing is drawn to show how the machine is assembled. Often a mistake in a detail drawing shows up on the assembly drawing which, therefore, also serves as a check on the earlier work.

The detail drawings and assembly drawings of a machine comprise the working drawings, from which the machine is made, as distinct from the design drawing or such drawings as display drawings intended for other purposes. The working drawings of a piece of machinery tell what manufacturing processes and materials are used, and how the different parts are finished, as well as the dimensions of the parts.

METALS

Metals are divided into two general types—ferrous and nonferrous. Ferrous metals are those whose major proportion is iron. Iron is the basis for all steels. Nonferrous metals are those whose major proportions are not iron, although they may contain a small amount of iron as an impurity.

Iron

Molten iron from the blast furnace may be further refined before it is allowed to cool, or it may be cast into shapes of approximately 80 pounds which are called pigs. In either case the product of the blast furnace is called pig iron. Pig iron is remelted with certain proportions of scrap to provide the desired chemical properties of iron for the manufacture of cast iron. Because of its brittleness and low tensile strength, cast iron is limited in use.

When pig iron is further refined through a process known as puddling, wrought iron is obtained. This iron is used in the manufacture of pipes, nails, and rivets.

Steel

Steel is made from molten iron from the blast furnace or from remelted pig iron by bringing it into contact with a liberal supply of oxygen which consumes the excess carbon and

Figure 12-20.—Schematic equivalent of an M-BWO.

With appropriate values of applied potentials and appropriate value and direction of magnetic field, the electron beam is formed in the gun regions, passes through the interaction region, and is collected at both the delay line and the collector.

In backward wave oscillators there is no RF input, and a portion of the delay line adjacent to the collector is modified to assure absorption of any power reflected from the output.

The principal projections from the main tube body are the RF output connector and the HEADER, through which the electrode leads are brought out to external terminals. A doughnut shaped magnet is used, since this form combines high internal magnetic field strength with excellent external magnetic self-shielding properties.

FREQUENCY TUNING AND MODULATION

The oscillator can be tuned through the designed range of frequencies by varying the delay line-to-cathode or sole-to-cathode potential. This can be done statically or dynamically at rates limited chiefly by modulating power and interelectrode capacitances.

The average rate of tuning for a given tube design will be nearly linear throughout the range and very similar from tube to tube. The sensitivity differs in present tubes of different frequency ranges from approximately 0.13 mc per volt at L-band frequencies to approximately 1.0 mc per volt at X-band frequencies. The sole potential can be varied for frequency modulation with the advantage of requiring less modulating power. Since frequency is determined by the anode-to-sole potential, both sole and anode (delay line) tuning sensitivities are essentially the same. Sole modulation is limited to one-half of the complete tuning range of the tube, due to tube electronic characteristics.

Amplitude Modulation

Amplitude modulation is accomplished by varying the accelerator potential, since this electrode controls delay line current. Accompanying the amplitude modulation is an inherent frequency modulation resulting from frequency pushing. (Frequency pushing is defined as an RF frequency variation due to a variation in anode current.) Pushing is not linear over either the frequency range or the current range. Amplitude modulation linearity is good, but may be limited at low modulation frequencies by cathode fatigue during high current peaks. The grid electrode should not be utilized for amplitude modulation purposes. A d-c potential on the grid may be required for optimum tube efficiency.

Pulse Modulation

Although these tubes have been designed primarily for CW operation, it is possible to pulse the accelerator electrode and obtain peak power output considerably in excess of the CW power. Some delay line current is present even at zero accelerator potential. In some cases, therefore, it may be desirable to bias the accelerator negatively to obtain complete cutoff, and pulse positively from the level of cutoff bias.

INSULATION AND COOLING

Normal heat dissipation, principally at the delay line and collector, usually requires that external liquid cooling be provided to this region. A coolant channel, an integral part of the delay line, serves this purpose, with coolant being provided through external connections.

994

some other impurities. Alloying elements are also added to steel to produce desired qualities.

Nonferrous Metals

One of the most important nonferrous metals is copper. Copper is an excellent conductor of electricity and has excellent resistance to salt-water corrosion.

Zinc is used as an alloying ingredient in making brass and some bronzes. It is also often used as a protective coating on steel sheets, which are then called galvanized sheets.

Tin is seldom used except as an alloying ingredient. Alloyed with lead, it makes a soft solder, and alloyed with copper, it produces bronze.

Aluminum is used extensively because of its light weight, easy workability, good appearance, high resistance to corrosion, and other desirable properties. When alloying elements such as magnesium, copper, nickel, and silicon are added, an alloy stronger than low carbon steel can be produced.

Nickel is a hard, malleable, and ductile metal. It is resistant to corrosion and is therefore often used as a coating on other metals. Combined with other metals, its effect is to make the alloy hard, strong, and ductile. It also imparts greater resistance to oxidation and corrosion.

True brass is an alloy of copper and zinc. Complex brasses are those containing additional alloying agents, such as aluminum, lead, iron, manganese, or phosphorus.

Bronze made of copper and tin was the best metal available for a great many uses before steelmaking techniques were developed.

Copper-nickel alloy is found extensively aboard ship because of its high resistance to the corrosive effect of salt water.

Monel contains nickel, copper, and small percentages of iron, manganese, and cobalt. In appearance, monel resembles stainless steel. In fact, it has many of the qualities of stainless steel. It has a very high resistance to corrosion.

K-monel is a special improved type of alloy that is stronger and harder than ordinary monel.

Inconel is a nickel alloy containing nickel, chromium, iron, and about 1 percent other elements. It has great resistance to corrosion and retains its strength at high temperatures. Exhaust systems of engines are often made of inconel.

Heat Treatment

Metals are heat treated to produce changes in their structure and physical properties. These changes are produced by variations in the temperature to which the metal is heated, the rate of heating, the time the metal is kept at the correct or critical temperature, the furnace atmosphere, and the cooling process and medium. There are several forms of heat treating. The most common for ferrous metals are annealing, normalizing, hardening, tempering, and case-hardening.

Hardness Tests

The property of hardness may be defined as the ability of a material to resist penetration. Because there are several methods of measuring hardness, the hardness of a material is always specified in terms of the particular test that has been used to measure this property, such as the Rockwell or Brinell. For example, R_c 44-48 means that the hardness of the metal part is between 44 and 48 on the C scale of the Rockwell Hardness Test.

Methods of Shaping Metals

Metals are often classified as being either cast metals or worked metals, depending upon the method used to shape them. Note, however, that even worked metals must first be cast into some sort of a shape such as an ingot. Mechanical working improves certain properties of the metal. Cold working, in particular, tends to improve strength and hardness and to produce a smooth surface. Hot working improves strength and toughness.

PLASTICS

Plastic materials are being increasingly used aboard ship. In some respects, they tend to surpass structural metals; plastic has proved to be shock resistant, not susceptible to salt water corrosion, and in casting, it lends itself to mass production and uniformity of end product.

MACHINE SHOP WORK

Machine finishing may be done by either cutting or grinding the metal or plastic away. Grinding produces a smoother surface and is

usually used only after a cutting process. The mass production of machine parts can be held within .001 in. accuracy, or even closer if necessary. Thus, a repair part for any machine fits and operates just as well as the original part. The most common cutting operations consists of turning, planing, milling, and drilling.

MACHINE DRAWING CONVENTIONS

The importance of the MIL-STDs has been indicated in both chapters 1 and 4. The MIL-STDs 1B, 2C, and 7A apply to all types of engineering drawings including machine drawing. Three of the MIL-STDs which have a more specific application to machine drawings are MIL-STD-8C Dimensioning and Tolerancing, MIL-STD-9A Screw Thread Conventions and Methods of Specifying, and MIL-STD-10A Surface Roughness, Waviness, and Lay. Some representative standards from these publications are included in some of the following sections.

Designating Materials

The typical machine detail drawing includes a material block and perhaps various notes which indicate the types of material to be used and their characteristics and quality.

Materials are usually specified by Federal or Military specification numbers. For example, the coupling on a particular oil burner is identified as "cast steel, class B, MIL-S-15083" and a lever on a particular safety valve is identified as "tool steel, MIL-S-15046," a clamp screw on a certain return flow burner is to be made of "brass, MIL-W-1165," or a washer in a certain safety valve assembly is to be made of "rolled corrosion-resisting steel, MIL-S-853."

In some cases, however, the materials are specified according to the SAE (Society of Automotive Engineers) system, according to the ASTM (American Society for Testing Materials) system, the AISI (American Iron and Steel Institute) system, or according to other metals classification systems.

For all practical purposes the AISI and SAE numerical designators for steel have the same meaning. AISI also has a letter prefix which indicates the method used in manufacturing the steel. Letters used as prefixes are:

A—open hearth alloy steel
B—acid Bessemer carbon steel
C—open hearth carbon steel
D—acid open hearth carbon steel
E—electric furnace steel

The SAE uses a four-digit identification number for steels. For the simpler alloys, the first digit indicates the alloy type; the second digit, the approximate percentage of the predominant alloying element; the last two digits, the carbon content in hundredths of 1 percent.

The first digit number and alloy types they represent are as follows:

1—plain carbon steel
2—nickel
3—nickel-chromium
4—molybdenum
5—chromium
6—chromium-vanadium
8—(was used to indicate national-emergency steel during World War II)
9—silicon-manganese

Nonferrous metals may be identified by their alloying elements. Examples are brass, bronze, coppernickel, and nickel-copper. Specific designations of an alloy are described by the amounts and chemical symbols of the alloying elements. For example, a copper-nickel alloy might be described as copper-nickel, 70 Cu-30 Ni. The 70 Cu represents the percentage of copper, and the 30 Ni represents the percentage of nickel.

Common alloying elements and their chemical symbols are:

Aluminum	Al
Carbon	C
Chromium	Cr
Cobalt	Co
Copper	Cu
Iron	Fe
Lead	Pb
Manganese	Mn
Molybdenum	Mo
Nickel	Ni
Phosphorus	P
Silicon	Si
Sulphur	S
Tin	Sn
Titanium	Ti
Tungsten	W
Vanadium	V
Zinc	Zn

In addition to the type of designations previously described, a trade name (such as Monel or Inconel) is used sometimes to designate certain alloys.

In addition to a material identification number, the material block on the drawing may include a "physical condition" and quality designation—that is, the designation of temper or other physical condition approved by a nationally recognized technical society or industrial association such as the American Iron and Steel Institute. Some of the physical condition and quality designations for various iron and steel products are listed here:

CR. . .	cold rolled	AQ. . .	aircraft quality
CD. . .	cold drawn	CQ. . .	commercial quality
HR. . .	hot rolled	DQ. . .	drawing quality
ANL. .	annealed	ERW .	electric resistance weld
NORM	normalized	S. . . .	seamless
EXTR.	extruded	AW . .	arc weld
NT. . .	normalized and tempered	BW . .	butt weld
QT. . .	quenched and tempered		

On the drawing, the heat treatment for a part may be indicated in several ways. A general note may list the steps, temperatures, etc. A hardness-test number or the tensile strength (psi) required for the part may be given.

Parts lists

A parts list may be required on a machine drawing. Such a list is usually placed on an assembly drawing and gives the name, quantity, material, stock size or weight, stock number, or drawing number of each part. A column may be added for remarks. Usually the larger or more important parts are listed first and the smaller or standard parts, such as screws, last.

When you make such a list, it is very important that you include every part. It is best to work out a system for taking the parts from the drawing and then later arrange the parts in order for the parts list. It is always wise to have your takeoff checked by someone else, since another man is less likely to make the same mistakes.

Gears

Though gears appear frequently on machine drawings, you usually do not have to draw the teeth in detail except for a few to indicate the proper dimensions.

The nomenclature of gears is illustrated in figure 6-1; the definitions of terms follow.

PITCH DIAMETER (PD).—Diameter of the pitch circle (or line) which equals the number of teeth divided by the diametral pitch.

NUMBER OF TEETH (N).—The diametral pitch multiplied by the diameter of the pitch circle (DP x PD).

DIAMETRAL PITCH (DP).—The number of teeth to each inch of the pitch diameter or the number of teeth divided by the pitch diameter. Diametral pitch is usually referred to simply as PITCH.

ADDENDUM CIRCLE (AC).—The circle over the tops of the teeth.

OUTSIDE DIAMETER (OD).—Diameter of the addendum circle.

CIRCULAR PITCH (CP).—Length of the arc of the pitch circle between the centers or corresponding points of adjacent teeth.

ADDENDUM (A).—The height of the tooth above the pitch circle or the radial distance between the pitch circle and the top of the tooth.

DEDENDUM (D).—The length of the portion of the tooth from the pitch circle to the base of the tooth.

CHORDAL PITCH.—The distance from center to center of teeth measured along a straight line or chord of the pitch circle.

ROOT DIAMETER (RD).—The diameter of the circle at the root of the teeth.

CLEARANCE (C).—The distance between the bottom of a tooth and the top of a mating tooth.

WHOLE DEPTH (WD).—The distance from the top of the tooth to the bottom, including the clearance.

Figure 6-1.—Gear nomenclature.

9971

FACE.—The working surface of the tooth above the pitch line.

THICKNESS.—The width of the tooth, taken as a chord of the pitch circle.

CIRCULAR PITCH is the distance in inches measured from the intersection of the face and flank of one tooth to the same point on the adjacent tooth. That is, it is equal to $\frac{PD}{N}$ or $\frac{\pi}{DP}$ On a rack, it is called linear pitch.

PITCH CIRCLE.—The circle having the pitch diameter.

WORKING DEPTH.—The greatest depth to which a tooth of one gear extends into the tooth space of another gear.

RACK TEETH.—A rack may be compared to a spur gear that has been straightened out. The linear pitch of the rack teeth must equal the circular pitch of the mating gear.

Although it is seldom necessary for the draftsman to draw gears in detail, he should know how to draw at least one form of gear with the teeth. For this reason, instructions on drawing an involute tooth form on a wheel and rack are included here. The diameter of the pitch circle (PD) on the wheel is given as 12 inches and the number of teeth (N) as 36.

1. Calculate the values in inches, to three decimal places when necessary, for each of the following dimensions:

DP (pitch) = $\frac{N}{PD}$.

WD (working depth of teeth) = $\frac{2}{DP}$.

A (addendum) = $\frac{WD}{2}$.

OD (outside diameter) = PD + 2A.

D (dedendum) = A = $\frac{WD}{2}$.

RD (root diameter) = PD - 2D.

CP (circular pitch) = $\frac{3.1416}{DP}$.

T (thickness of teeth) = $\frac{CP}{2}$.

Figure 6-2.—Approximate method of drawing teeth on a wheel and rack.

9972

2. Locate the center of the wheel and draw the pitch circles with a radius of 1/2 the pitch diameter. Draw the center lines of the wheel, and at the point where the vertical centerline intersects the bottom of the pitch circle, draw a horizontal line to represent the pitch line of the rack. (See fig. 6-2A.)

3. In order to draw the teeth by the approximate method given here, a circle called the base circle, which falls between the pitch circle and the root circle, must be drawn. In order to locate this circle, draw a line inclined at an angle of 15° through the intersection of the vertical center line and the pitch circle, and a second line from the center of the wheel inclined at an angle of 15° to the vertical centerline. (See fig. 6-2B). The distance from the intersection of these two lines and the center of the wheel is the radius for drawing the base circle. Fifteen degrees was selected because it is a convenient angle to draw and closely approximates the 14 1/2° pressure angle of the teeth.

4. Set the small dividers at a distance equal to the thickness of the teeth and lay off the teeth on the pitch circle and then on the pitch line of the rack. The sides of the teeth in the rack are drawn at an angle of 15° with the vertical, as shown in figure 6-2 E. The sides of the teeth in the wheel are drawn with a radius r as indicated in figure 6-2D.

5. With a center on the baseline, draw an arc with a radius of x to y through one of the points laid off with the dividers and repeat the procedure for all other points. In order to determine where the center should fall on the base circle, first draw an arc cutting the base circle with a center on one of the points on the pitch circle. Both sides of the teeth may be drawn by this method. (See fig. 6-2 D.)

Figure 6-3.—Representations of common types of helical springs.

Figure 6-4.—Single line representations of springs.

6. In completing the teeth of the wheel, draw fillets with a radius of 1/16 inch connecting the sides of the teeth with the clearance circle. There are no fillets in the rack shown in this drawing. (See fig. 6-2D.)

Helical Springs

A true orthographic projection of a helical spring would be drawn by first laying out a true helix as a center line of the spring, then drawing circles of the diameter of the wire, and then enclosing the circles with curved lines.

This true method is seldom used, however, and springs are usually drawn with straight lines. In this case, the only difficulties may consist of getting the correct number of coils in the required space and finishing the squared or ground ends. Sometimes the neatest and most satisfactory way of drawing a spring is in cross section. Figure 6-3 shows views of common types of helical springs. Note that the ends may be squared, ground, or both squared and ground. As shown in figure 6-4, springs may be drawn as single lines on working or assembly drawings.

Screws

The terminology used in referring to screw threads is illustrated in figure 6-5. Definitions are as follows:

SCREW-THREAD.—A ridge of uniform section in the form of a helix on the external or internal surface of a cylinder.

HELIX.—The curve formed on any cylinder by a straight line in a plane that is wrapped round the cylinder with a forward progression.

EXTERNAL THREAD.—An external thread is a thread on the outside of a member. Example, a thread on a bolt.

Figure 6-5.—Screw-thread terminology.

INTERNAL THREAD.—A thread on the inside of a member. Example, the thread inside a nut.

MAJOR DIAMETER.—The largest diameter of an internal or external thread.

AXIS.—The center line running lengthwise through a screw.

CREST.—The surface of the thread corresponding to the major diameter of an external thread and the minor diameter of an internal thread.

ROOT.—The surface of the thread corresponding to the minor diameter of an external thread and the major diameter of an internal thread.

DEPTH.—The distance from the root of a thread to the crest, measured perpendicularly to the axis.

PITCH.—The distance from a point on a screw thread to a corresponding point on the next thread, measured parallel to the axis.

LEAD.—The distance a screw thread advances in one turn, measured parallel to the axis. On a single-thread screw the lead and the pitch are identical; on a double-thread screw the lead is twice the pitch; on a triple-thread screw the lead is three times the pitch.

It would often take days of a draftsman's time to draw the screw threads for one drawing if he followed strict orthographic projection as shown in figure 6-5. In actual practice the threads are drawn as straight lines, rather than as the curve formed by a helix, or they may be further simplified. Semiconventional thread drawings are shown in figure 6-6. Figure 6-7 shows regular thread symbols, and figure 6-8 shows simplified thread symbols.

To draw semiconventional external screw threads:

1. Draw the center line and draw lightly the lines defining the major diameter of the threads. (See fig. 6-6a.)

2. On the upper line, mark off spaces the width of the pitch. If there are 8 threads to an inch, the pitch will be 1/8 inch on a full-size drawing. (See fig. 6-6b.)

3. On the lower line, mark off one space which is 1/2 the pitch; then mark off the pitch for the rest of the threads. (See fig. 6-6b.)

4. From each pitch point on both upper and lower lines, draw short lines which slope 60° from the center line. (See fig. 6-6c.)

5. Then turn your triangle over and draw line sloping at 60° to meet with the other 60° lines thus completing the outline of the threads. (See fig. 6-6d.)

6. Connect the crests of the threads as shown in figure 6-6e.

7. Connect the roots of the threads in the same manner (See fig. 6-6f.)

9974

Figure 6-8.—Simplified external and internal thread symbols.

Figure 6-9.—Steps in drawing an unfinished square bolt head.

To draw internal threads when they are shown in cross section, follow the same general procedure. (See fig. 6-6g.)

When the threads are to be shown with hidden lines, they should be drawn as in figure 6-6h.

Figure 6-7 shows how regular thread symbols are drawn. External threads are indicated by lines which are usually not slanted. The line from crest to crest is drawn as a light line and the line from root to root is drawn as a heavy line. No effort is made in drawing external threads to show the outline form of the threads. In cross section, the thread outline of the external threads is still drawn. Internal threads are drawn with dotted line indicating the major and minor diameters. In cross section, internal threads are drawn with the lines of the threads, a light line crest to crest and a heavy line from root to root.

The simplified thread symbols are shown in figure 6-8. The line of the minor diameter along the roots of the threads is shown as a dotted line on both internal and external threads. No thread cutlines are drawn and no lines are drawn from crest to crest or from root to root.

Bolts and Nuts

Bolts may be unfinished, semifinished, or finished. Unfinished bolts are made by forging and rolling processes. On semifinished bolts, the surface under the bolt head is machine finished to provide a washer-faced bearing surface. This means that a round raised surface which has a diameter approximately equal to the width across flats in machined on the bearing surface, or the corners of the under face are chamfered. Finished bolts are machined all over to serve some purpose or to improve their appearance.

Although a draftsman is seldom called upon to make detailed drawings of standard bolts, he is very often required to make a drawing of a special bolt which may have a standard head or a standard shaped nut. Figure 6-9 and figure 6-10 illustrate the steps in drawing bolt heads. Nuts are drawn the same way. The nut for a bolt of a particular size is usually larger than the bolt head.

The tops of wrench-head bolts are chamfered at the corners. On the bolt this chamfer is at an angle of 25° to 30° and for convenience it is always drawn at an angle of 30°. The bearing surface may be unfinished, finished with a raised washer face, or finished by chamfering the corners. On the thread end, bolts are chamfered at an angle of 45° to the depth of the thread.

Finish Marks

The military standards for finish marks are set forth in MIL-STD-10A. Many metal surfaces must be finished with machine tools for various reasons. The acceptable roughness

Figure 6-12.—The old finish symbol.

Figure 6-13.—Methods of placing surface roughness symbols.

Figure 6-14.—Typical examples of symbol use.

The coolant generally used is Dow Corning 200 silicone oil, a thermally stable oil with a high resistance to change in temperature. For high altitude operation, the input bushing can be pressurized or immersed in an insulating liquid. In some applications, the tube is operated with the cathode at ground potential. When this method is used, primary to secondary high voltage insulation of the various supply transformers is unnecessary; but high voltage isolation of the RF output connector is necessary and additional safety precautions are required.

SPECIAL CONSIDERATIONS

Most microwave tubes have characteristics which limit their use or which require special consideration in their use. The following is a list of these factors, which the designer must bear in mind as he uses the tube in a system and which are also of interest to the operator:

1. Voltage tuning sensitivity at X-band frequencies is approximately 1 mc per volt. Thus, for a CW signal, the power supply must be well regulated, with a low ripple factor. Although the average tuning sensitivity is nearly linear over the frequency range, there are variations in sensitivity for small frequency changes.

2. The sole current changes in magnitude with frequency tuning, and it can be in either direction.

3. Frequency pushing results from variations of other tube parameters. This may or may not be significant.

4. Interelectrode leakage current of a small value exists in tubes of present design.

5. A small amount of frequency pulling is a characteristic of the M-BWO. These tubes are, therefore, somewhat susceptible to load VSWR (voltage standing wave ratio) variations. Generally, load isolators are not required when load VSWR's are equal to or less than 1.5 to 1.

6. After full beam current has been established, stabilized frequency will be reached in 2 minutes or less.

7. Interelectrode capacitances must be considered as modulating frequencies are increased.

8. Power output varies over the tuning range primarily due to the necessary change in input power when tuning. Therefore, a 3-db power variation may be encountered over the tuning range.

THE BEAM MISER

The BEAM MISER is a unique type of depressed collector utilized in the beam type, crossed field traveling wave tubes. It permits significant increase in efficiency and power with no additional external connections or other changes in tube or circuit. The depressed collector is one which operates at a lower voltage than the anode or delay line, rather than at the same voltage.

The beam miser consists of a collector internally connected to the cathode and consequently at cathode potential. Thus the anode current is reduced for a given beam current, or the beam current is increased for a given anode current. In an analogous sense, the beam miser has some of the advantage of a reentrant electron beam in crossed field tubes. A considerable part of the spent beam which is unused can be returned to the cathode instead of being wasted by normal collection at anode potential.

The use of a beam miser in standard M-BWO's has permitted increases of power of the order of 30 percent for normal operating anode currents. It has also permitted suitable operation of one tube at several power levels; that is, multiple operating current capability. A tube with a beam miser requires no external mechanical changes or additional electrical input connectors and is, therefore, directly replaceable in the same socket as a standard tube not having a beam miser.

PARAMETRIC AMPLIFIER

The parametric amplifier, or reactance amplifier, is a device capable of low-noise amplification in the UHF and microwave regions of the electromagnetic spectrum. Seldom has a device gone so rapidly from the laboratory into operation. The low-noise amplification afforded by these devices offers phenomenal radar range improvements on existing equipments with minimum cost and maximum economy.

The parametric amplifier increases the power level of a signal by means of the variation of an energy-storage parameter. An everyday example is that of a child on a swing. The oscillation is maintained by "pumping"; that is, the child lowers his center of gravity on the downswing and raises it on the upswing. For maximum oscillation, the pumping takes place at twice the frequency of oscillation.

995

of a surface depends upon the use to which the part will be put. Sometimes only certain surfaces need to be finished. To indicate these surfaces and to specify the degree of finish desired, a modified V symbol is used with a number or numbers above it. On a drawing, this symbol touches the line which represents the surface to be finished. The proportions of the surface roughness symbol are shown in figure 6-11. On small drawings the symbol should be proportionately smaller.

In the past, an inclined f crossing the line that represented a surface was used as a finish mark. (See fig. 6-12.) You may have occasion to handle old drawings on which this symbol appears, and you must understand what it means in order to read them. However, you should not use this symbol on your own drawings.

The number in the angle of the check mark tells the machinist what degree of finish the surface should have. It indicates the root-mean-square value of the surface roughness height in millionths of an inch. In other words, it is a measure of the depth of the scratches made by the machining or abrading process.

Wherever possible, the surface roughness symbol should be drawn touching the line representing the surface to which it refers. If space is limited, the symbol may be placed on an extension line from that surface or on the tail of a leader with an arrow touching that surface. (See fig 6-13.)

When a part is to be finished to the same roughness all over, a note on the drawing should include the direction FINISH ALL OVER, along with the finish mark and the proper number. For example, FINISH ALL OVER 125√. When

Figure 6-15.—Relation of symbols to surface characteristics.

a part is to be finished all over but a few surfaces vary in roughness, the surface roughness symbol and number or numbers should be applied to the lines representing these surfaces and a note on the drawing should include the surface roughness symbol for the rest of the surfaces. For example, 125√ ALL OVER EXCEPT AS NOTED. (See fig. 6-14.)

The machining operation to be used in finishing a surface is not usually specified. A good machinist will use the best machining operation he can for any given surface. However, certain surfaces can be obtained only by operations such as buffing, lapping, scraping, and honing, and these should have the surface roughness specified by the surface roughness symbol and number, followed or preceded by a notation of the required operation. For example, 4√ LAP.

In addition to surface roughness, the waviness and lay may be indicated on the drawing. As shown in figure 6-15, surface roughness has a width, which is the distance between successive peaks or ridges which constitute the predominant pattern of the surface roughness. Waviness is irregularities which are of greater spacing than the roughness. Lay is the direction of the predominate surface pattern produced by tool marks or grain of the surface. Typical symbols for lay and waviness are shown in figure 6-15; the lay symbol shown means that the lay is to be perpendicular to the boundary line representing the surface to which the symbol applies. Other lay symbols are described in MIL-STD-10A.

Dimensions and Tolerances

As explained in chapter 4 and mentioned earlier in this chapter, MIL-STD-8C covers in detail the conventions for dimensioning and tolerancing drawings. The following paragraphs contain information which is typical of that presented in MIL-STD-8C.

Limits are the maximum and minimum values prescribed for a specific dimension. A tolerance represents the total amount by which a specific dimension may vary. As mentioned in chapter 4, tolerances may be shown on drawings by several different methods. In the unilateral method (A of figure 6-16), the minimum or the maximum measurement is used as the dimension figure, and the difference allowable is given as a plus or minus tolerance figure. In the bilateral method (B of figure 6-16), the dimension figure indicates the plus or minus variation that is acceptable. In the limit dimensioning method (C of figure 6-16), the maximum and minimum measurements are both stated.

The surfaces being toleranced have geometrical characteristics such as roundness, or perpendicularity to another surface. Typical geometrical characteristic symbols are shown in figure 6-17. A datum is a surface or line or point from which a geometric position is to be determined or from which a distance is to be measured. Any letter of the alphabet except I, O, and Q may be used as a datum identifying symbol. A feature control symbol is made of geometric symbols and tolerances. As shown in figure 6-18, the feature control symbol may also include datum references.

The following are typical of the hundreds of abbreviations contained in MIL-STD-12B:

DIA	Diameter
GR	Gear
HDN	Harden
HT	Heat
PD	Pitch Diameter
REF	Refer or Reference
TIR	Total Indicator Reading
TOL	Tolerance

These abbreviations together with many of the previously discussed symbols and designations may be seen on the typical drawing in figure 6-19.

Round holes are dimensioned in various ways, depending on design requirements and manufacturing methods. The dimensioning methods in figure 6-20 are common machine drafting practice.

Countersinks for flat head screws, rivets, and similar items are specified on drawings as shown in figure 6-21. The linear dimension used for the specification is the diameter of the top of the countersink. The abbreviation CSINK indicates shape only and does not restrict the methods used to produce this shape. The dimensions of the countersink are determined by the dimensions of the screw or other part which is to fit in it. The angle indicated is the interior angle between the sloping faces of the countersink.

Counterbores are for recessing round-head screws and the like below the level of the main surface. Counterbores are dimensioned by a leader note giving the abbreviation CBORE

Figure 6-16.—Methods of indicating tolerance.

9381

Figure 6-19.—Detail drawing of a base pivot.

Figure 6-20.—Dimensioning round holes.

Figure 6-22.—A counterbored hole.

and dimensions for the diameter and depth of the counterbore, as shown in figure 6-22.

Internal threads are usually cut in a drilled hole with tools called taps. The threaded holes are called tapped holes. After the hole has been drilled, the threads are started with a taper tap. The taper or starting tap is slanted toward the end, which means that not as much strain is placed on the threads of the tap as there would be if an attempt were made to finish the threads with a single tool. After the threads are well started, a plug tap is used, followed by a bottoming tap if it is necessary to make full-size threads to the bottom of a drilled hole. When the bottoming tap is used, the 120° angle of the drill will still be visible below the tapped threads as shown in figure 6-8.

Tapped holes that are to be threaded to the bottom are dimensioned on a drawing by a note which indicates the tap drill diameter and the depth of the drilled hole, as well as the thread notation and the depth of the thread.

When it is necessary to show the location of holes in relation to other elements on the drawing, they should be located by dimensions to extensions of center lines. Nonprecision holes may be located by the angular dimensioning system, provided their centers lie on a common circle. Precision holes generally should be located by rectangular dimensions. Holes should never be located by drawing extension lines to their circumferences.

In instances where there are a large number of fillets or rounds of the same size, it is acceptable to specify their radii in the form

Figure 6-21.—A countersink hole.

Figure 6-23.—Methods of dimensioning a chamfer.

of a note instead of specifying each individual radius. The following notes, with radius indicated in the blanks, may be used where they are appropriate and may be combined when necessary.

ALL EDGES - - - - - R UNLESS OTHERWISE SPECIFIED.
ALL FILLETS- - - - R UNLESS OTHERWISE SPECIFIED.

When the thickness of a curved wall is uniform, specify the radius on the inside or on the outside, but not on both sides of the same wall.

A spot-face is an area around a hole which is machined sufficiently to provide a seating surface for a bolt head, nut, washer, or similar item. It is not necessary to show a surface roughness symbol for a spot-face. A spot-face is specified by a leader to the surface to be spot-faced, with a note including the abbreviation SFACE and the minimum diameter. This leader and note may be combined with the leader and note used to specify the diameter of a concentric hole.

A chamfer is simply a bevel where a sharp angle of two adjoining surfaces has been removed, and this occurs in many places on machines and machine tools. A chamfer on a screw head which is to fit in a countersunk hole is dimensioned with a note giving the angle. Forty-five degree chamfers are dimensioned as shown in figures 6-23a and 6-23b. Other chamfers are dimensioned by giving the length and the angle as shown in figure 6-23c. It is unnecessary to use the word chamfer on the drawing.

Slots with rounded ends should be dimensioned by giving the over-all length of the slot together with the width and the radius as shown in figure 6-24.

External surfaces with rounded ends should be dimensioned by specifying the over-all length and width of the piece and the radius of the ends as shown in figure 6-25. Holes or other features should be dimensioned as shown in figure 6-26.

Figure 6-24.—Dimensioning a slot with rounded ends.

SHIP STRUCTURAL DRAWINGS

Because of the shape of a naval vessel, the usual plan and elevation drawings are inadequate for the purpose of locating all points and defining all structures. Instead a system of fundamental lines and sections are used. The hull of a ship is considered to be cut by a series of horizontal, vertical, and transverse planes, with a result similar to the subdivision of an egg crate or an ice cube tray.

All vertical measurements aboard a ship are calculated from the plane of the base line (BL). The base line plane extends horizontally from an established point at the bottom of the ship, usually along the top of the flat keel. For convenience in measuring above the base line, a series of waterlines (WL) are established. Each waterline is a certain number of feet from the base line. In figure 6-27, the water lines are shown at the intersection of the horizontal planes 1, 2, and 3 with the hull. When these waterlines are superimposed

one upon another, they form the plan view of the ship, as shown in the lower part of figure 6-27. The upper half of this plan as shown in the figure is known as the half breadth plan.

Horizontal measurements aboard a ship are calculated in terms of buttock lines and stations. Transverse measurements are calculated from the centerline. In figure 6-28, the vertical plane A passes through the exact fore-and-aft centerline, and is termed the vertical centerline plane of the ship. Its intersection with the hull shows the centerline profile and the exact contour of the stem and stern. Outboard from the centerline, a series of planes, shown by B and B' in the figure, are called buttock planes. Their intersections with the hull form the buttock lines, which are labeled according to the number of feet between each and the centerline. Superimposing the buttock lines one upon another gives the sheer plan of the ship, as shown in the lower part of figure 6-28.

In order to show the complete shape of the ship, another set of lines, called frame lines are used between the forward and after perpendiculars. They are numbered progressively

Figure 6-27.–Drawing showing horizontal planes and half-breadth plan.

Figure 6-28.—Vertical centerline plane, buttock planes, and sheer plan.

from fore to aft. The distance between each of these lines varies with the different types of ships. These lines are defined by the intersection of transverse planes with the hull of the ship, as shown in figure 6-29. Such an intersecting plane is called a station. The outline of the hull as intersected by a station is a section. If the frame lines are shown superimposed one upon the other as in the lower portion of figure 6-29, the resulting drawing is called the body plan of the ship.

Some ship hulls are symmetrical with respect to the vertical centerline plane, only one side of the waterlines (port or starboard) need be shown to give the full shape of the hull. Therefore, only half of the plan view, or the half-breadth plan, is ordinarily used. (See upper sketch of fig. 6-30.) Since there is the same symmetry in the body plan, the right half of this plan shows the successive frame lines from the midship section forward, and the left hand side shows the frame lines from the midship section aft. This combination, shown in the middle of figure 6-30 makes for clarity, requiring fewer lines to represent the hull sections. The lower view of figure 6-30 shows the plan with the buttock lines in their true shape.

An additional set of planes is sometimes used, as shown in figure 6-31. These planes are perpendicular to the stations, intersect the

Figure 6-30.—Projection of half-breadth plan, body plan, and sheer plan.

Figure 6-29.—Drawing showing transverse planes and body plan.

Figure 6-31.—Drawing showing projection of the bilge diagonals.

vertical centerline plane at a point slightly below the main deck, and extend out through the hull at the turn of the bilge (the curved section of the hull joining the sides with the bottom). At their intersection with the hull, they form curved lines called the bilge diagonals. As can be seen, the various waterlines, stations, buttock lines, and bilge diagonals completely illustrate the shape of the proposed ship.

In order to understand a discussion of ship drawings, you should have a comprehension of the terms in the following paragraphs.

In the half-breadth plan, we generally speak of the waterlines as the lines developed by the intersections of successive horizontal planes with the hull of the ship, from the keel upward to the weather deck. Among this set of waterlines we have one at which the ship has been designed to float under normal loaded condition. The waterline is called the designer's waterline (DWL). (See fig. 6-32.)

One common misconception is that the keel extends downward from the bottom of the ship. This is true only in the case of small boats with bar keels. On large ships, however, use is made of secondary keels outboard of the flat keel, called docking keels. These are relatively strong longitudinals, which simplify support of the ship when it is in drydock. Also, bilge keels are present on many larger ships. These are triangular or flat plate keels projecting from the hull at the turn of the bilge, running fore-and-aft for approximately two-thirds the length of the ship, and serving to help reduce the roll of the ship in a seaway.

Length of a ship is expressed in two ways: length over-all and length between perpendiculars. In the first case, the length is measured from the extreme forward end to the extreme after end of the ship. The length between perpendiculars extends from the forward perpendicular (FP) to the after perpendicular (AP), the perpendiculars being vertical lines passing through the line and the designer's waterline at its intersection with the bow and stern of the vessel in the sheer plan. Length between perpendiculars is sometimes called waterline length. (See fig. 6-32.)

Draft, or vertical distance from the surface of the water to the bottom of the ship's keel, is measured at the bow and at the stern by scaled markings on the hull. Draft, then, is generally spoken of as draft forward and draft aft. The average of these two readings is known as mean draft.

Trim is defined as the angle to the horizontal at which a vessel floats. In general, this is the angle between the designer's waterline and the actual waterline at which the ship is floating. If the draft forward is greater then the draft aft, the trim of the ship is changed, the numerical value of this change is the algebraic difference of the changes in draft forward and aft.

Figure 6-32.—Drawing illustrating use of certain terms.

Figure 6-33.—Draft of a ship.

9987

As an example of the above statements: if a ship is trimmed so that she draws 21 feet 0 inches aft and 19 feet 0 inches forward, she is down by the stern and her mean draft is 20 feet 0 inches. By thus changing the trim, we have decreased the draft forward by 12 inches, and we have increased the draft aft by 12 inches. Thus, the change of trim is a plus 12 inches aft minus a negative 12 inches forward which equals 24 inches, as illustrated in figure 6-33.

Frequently, a ship's characteristics are improved if she has a slightly greater draft aft. When a ship is so designed, she is said to have been designed with a drag.

Dealing with measurement of the above-water portion of the ship's hull, we have freeboard, or the vertical distance from the water to the weather-deck edge at any point. Sheer is the excess of freeboard forward or aft over the amidships.

One never speaks of a ship's width, but rather of her breadth, or beam, which is the athwartship measurement taken at the broadest point of the hull.

When a ship is first floated, it will sink to a draft at which it displaces a weight of water equal to the weight of the ship. Therefore, we speak of a ship's weight as its displacement in tons. Displacement is always measured in long tons; that is, 1 ton equals 2,240 pounds.

The basic structural component of a warship is flat steel used to form the shell, decks, and bulkheads of the ship. Such pieces are subdivided into two types: sheets and plates. Those having a weight of 5 pounds per square foot of surface or less are known as sheets. Those having a weight of over 5 pounds per square foot of surface are known as plates.

The major parts of the structural steel used in ship construction is plating which usually comes in rectangular shapes. The shell of the ship is made up of fore-and-aft rows of plating known as strakes. The junction of plates within a strake is a butt, while the connection between the plates of adjacent strakes is called a seam. These plates are fastened together to form seams and butts by means of riveting or welding.

In general, three types of plates are used in ship construction:

1. Flat plates, which are the most common type on the sides, bottom, bulkheads, and decks of a vessel.

2. Rolled plates are those having curvature in one dimension only. The most common uses are at the turn of the bilge. They are formed cold on a roller in a shop.

3. Furnaced plates are those plates having curvature in two or three dimensions. It is necessary in this case to heat the plate and shape it while hot. The plates around the outboard propeller shaft bearings, which are called boss plates, are usually furnaced because of the large amount of shaping necessary. The plates in the lower section of the bow are also usually furnaced plates.

The common structural shapes used in ship construction are shown in figure 6-34. Of these, the I-beam and T-bar are most widely employed. These shapes are rolled to size and form in the steel mills and are delivered ready for use. Shapes similar to those shown in figure 6-34, but of larger than normal manufacturing size are built up from plates and angles, as shown in figure 6-35.

The keel (K) of a ship is frequently referred to as the backbone of the hull. It is a built-up girder consisting of the central vertical keel (CVK), the dished or flat keel plate, and the rider plate or keelson plate. The flat keel or central bottom strake is always of

Figure 6-34.—Common structural shapes used in ship construction.

9988

The principle of operation can be illustrated by an L-C resonant circuit in which the spacing of the capacitor plates is varied cyclically by a "pump" at a frequency twice the signal frequency which is identical to the resonant frequency of the circuit. (See fig. 12-21.)

The circuit has a resonant frequency f as indicated by the capacitor voltage as a function of time. Imagine that the capacitor plates can be physically separated and returned to the original separation. If the capacitor plates are separated at A when the voltage is at maximum, there is a decrease in capacitance and a corresponding increase in voltage. (Since E = Q/C, the total charge Q on the capacitor must remain what it was when the voltage reached its peak value.) Work is done when the plates are pulled apart to separate the charge. The total energy in the system has been increased by the source which separated the capacitor plates. The energy transfer is referred to as pumping, and the source supplying the energy is referred to as the pump.

From point A, the capacitor begins to discharge and the energy which was stored in the electric field between the capacitor plates is converted into energy in the magnetic field surrounding the inductance L. If the plates of the capacitor are returned to their original separation at B when the voltage goes through zero and there is no charge on the plates, no work is done and the voltage is unchanged. If the capacitor plates are separated when the voltage is at the maximum negative point C, additional energy is supplied to the system.

In order to obtain maximum amplification, the plates must be separated at the precise maximum positive and negative points (A and C), and they must be returned to their original position B at the precise instant when the voltage is zero between the capacitor plates.

Figure 12-21. —Capacitor plates varied by a pump.

The frequency of the pumping source is twice the resonant frequency of the tank circuit. If the phase of the pump input and the resonant frequency of the tank circuit are not correct, the resultant gain will be somewhat less than achieved under a phase-locked condition.

In a practical case, the separation of the signal frequency and the pump frequency cannot be conventiently maintained constant, but will drift in and out of the optimum condition periodically, resulting in modulation of the signal frequency. Thus, the output will contain the pump frequency, signal frequency, and the pump frequency minus the signal frequency. (The latter is called the idler or image signal.)

Several devices may be used to provide operation in the parametric mode. One is the silicon diode which is used as a silicon capacitor since it has low-noise and high frequency characteristics. Another device is the reactance tube which can provide the pump action by periodically, varying the capacitance in response to an input signal. By the use of the nonlinear characteristics of ferromagnetic and ferroelectric materials, parametric amplification can also be achieved.

There are three basic configurations of the parametric amplifier. (See fig. 12-22.) They are as follows:

1. Two-port sum-frequency (or upper sideband) up-converter.
2. Two-port difference-frequency (or lower side-bank) down-converter.
3. One-port difference-frequency parametric amplifier.

In the two-port sum-frequency arrangement, the overall noise figure is higher than other modes of operation, and the amplifier has only moderate gain due to the restrictions placed upon the varactor at maximum pump frequency. However, it does have a wide bandwidth. In the two-port difference-frequency mode of operation, the amplifier has a relatively narrow bandwidth, high gain, and a low-noise figure.

In the one-port difference-frequency mode, the parametric amplifier has the lowest noise figure. It is also fail-safe in that the system would continue to operate with near the same noise figure if the pump were to fail. However, a circulator must be used to separate the amplified output from the incoming signal; this also aids in maintaining amplifier stability

Figure 6-35.—Examples of built-up shapes; diagram on the left shows welded construction diagram on right shows riveted construction.

extra strength although of less than standard breadth. Joining the flat keel is the bottom plating. Figure 6-36 illustrates the structure of a typical keel.

Members extending to the sides of the vessel and joined perpendicularly to the central vertical keel are called floors. Floors may be closed and watertight, or they may be open. (See fig. 6-37.) Extending the length of the vessel are other members called longitudinals. The floors and longitudinals divide the bottom of vessels into compartments. Steel plating over the floor and longitudinals forms the inner bottom, which may also be called the tank deck. On cargo ships, frames are installed on the sides as continuations of the floors. On cruisers, floors run up to the lowest complete deck, and above this deck, web frames are installed.

The outside plating of the ship is called the shell plating. The entire vessel may be considered a horizontal box girder, and shell plating contributes greatly to the strength of that girder. Figure 6-38 illustrates the types of strakes used in building up the shell. Each strake is lettered alphabetically, starting on each side of the keel and continuing to the sheer of the ship. The letter I is usually omitted to avoid its being confused with J. The A strakes, joining the flat keel, are called garboard strakes. The final strake at the edge of the deck is called the sheer strake because it follows the sheer or longitudinal curve of the ship's profile.

An important strength function of decks is the support against racking (twisting) that they give to the ship. Certain decks are designed

Figure 6-37.—Open and closed floors.

Figure 6-36.—Keel structure.

Figure 6-38.—Diagram showing types of strakes.

for protective purposes against plunging shell fire or aerial bombardment. These decks are designated as ballistic decks, or protective or splinter decks, and are fitted with plating of extra strength and thickness.

In warship construction all decks are watertight. They generally extend the full width of the ship but not necessarily the full length. A complete deck is one which extends the full length of the ship. A deck which does not extend the full length is known as a partial deck. The main deck is always a complete deck. The first complete deck below the main deck is called the second deck. Where there are several complete decks below the main deck, they are known as the second deck, the third deck, etc. A partial deck which is above the lowest complete deck is known as a platform. Where there are two or more partial decks below the lowest complete deck, they are known as the first platform, the second platform, etc. A deck which is laid a small distance above the inner bottom in the machinery spaces is known as a flat, and has no camber. The flats in the machinery spaces are not watertight, and ordinarily are composed of separate plates which are easily removable.

A deck which has more than ordinary sheer is known as an inclined deck. The relationship of decks are shown in figure 6-39.

In order to reinforce the deck beams and relieve the deck beam brackets and side frames

Figure 6-39.—Composite diagram showing the relationships of decks.

fcc 9990

of the total load, vertical stanchions, or pillars, are fitted between decks. These are of various sizes and construction, some being simple round sections, solid or hollow, and others being built up of various plates and shapes riveted or welded together. A form often used, the pipe stanchion, consists of a wrought iron or steel tube fitted with special pieces for securing it to the deck beams at its upper end, or head, and lower end, or heel.

A bulkhead is a vertical partition extending athwartship or fore-and-aft of a vessel. A bulkhead may be watertight, oiltight, airtight, or nonwatertight. Watertight bulkheads subdivide the internal space of a ship into a number of compartments.

Figure 6-40.—Types of bulkhead stiffeners.

Like decks, bulkheads consist of plating and reinforcing bars. In the case of bulkheads, the reinforcing bars are known as bulkhead stiffeners. Types of bulkhead stiffeners are shown in figure 6-40. The bulkhead stiffeners usually are placed in the vertical plane, and are secured at the top and bottom and to any intermediate deck by brackets attached to the deck plating. The size of the stiffeners depends upon their spacing, the height of the bulkhead, and the hydrostatic head which the bulkhead is intended to withstand.

The design of the bulkhead and the bulkhead stiffener must be such that the structure is strong enough to resist excessive bending or bulging in case of flooding in either of the compartments of which it forms a boundary.

Every space in a ship is assigned an identifying letter-number symbol. This symbol indicates the deck, the location of the compartment in both a fore-and-aft direction and in its athwartship relation to the centerline, and the use of the compartment. For a detailed description of compartment designation, see chapter 11 of Basic Military Requirements, NavPers 10054-B.

WELDING DRAWINGS

The various structural steel shapes which make up the structure of a ship are generally connected together by welding, which is the process of fusing the parts into one body by the application of heat. The heat source may be burning gas or electricity. There are numerous processes of welding. There are various types of welded joints such as butt joints, corner joints, lap joints, tee joints, and so on; the name of the joint is descriptive of the positioning of the members to be joined. There are many types of welds such as bead welds, fillet welds, groove welds, and so on. All of these elements plus much additional detail may be shown on drawings by means of welding symbols and weld symbols.

For BuShips applications, the welding symbols to be used are set forth in American Welding Society Standard AWS A2.0-58. Typical symbols are shown in figures 6-41, 6-42, and 6-43. Figure 6-41 shows the welding symbol with the weld arrow. The arrow serves as a base on which all symbol information is placed in standard locations. The basic and supplementary symbols used to denote weld requirements for any given weld are also included. The weld symbols in their respective positions on the reference line and arrow, together with dimensions and other data, form the welding symbol. The assembled welding symbol consists of the eight elements listed below, or as many of them as are necessary to show the requirements of a given weld. Finish symbols indicate the method (C = chipping, M = machining, G = grinding)

BASIC ARC AND GAS WELD SYMBOLS							
BEAD	FILLET	PLUG OR SLOT	GROOVE				
			SQUARE	V	BEVEL	U	J

BASIC RESISTANCE WELD SYMBOLS				SUPPLEMENTARY WELD SYMBOLS			
SPOT	PRO-JECTION	SEAM	FLASH OR UPSET	WELD ALL AROUND	FIELD WELD	CONTOUR	
						FLUSH	CONVEX

Figure 6-41.—Standard location of elements and types of welding and weld symbols.

Figure 6-42.—Elements of a welding symbol.

of finishing, not the degree of finish. The eight elements of an assembled welding symbol are:

- Reference line
- Arrow
- Basic weld symbols
- Dimensions and other data
- Finish symbols
- Supplementary symbols
- Tail
- Process specifications, or other references.

To help clarify the reading of the eight elements of a welding symbol, refer to figure 6-42; each element is illustrated separately. The following is an explanation of each portion of figure 6-42.

1. This shows the reference line.

2. This shows the arrow. The arrow points to the location of the weld.

3. This shows the basic weld symbols. In this case it is to be a fillet weld and it is to be located on the arrow side of the object to be welded (explained in figure 6-43.)

4. This shows the dimensions and other data. The dimensions here indicate that the weld is to be 1/2 inch thick and 2 inches in length (L = length of weld, figure 6-41), and that the center to spacing (P = pitch of weld, figure 6-41) of the welds is to be 4 inches.

5. This shows the supplementary symbols (fig. 6-41). The supplementary symbol here indicates that the weld is to be convex.

6. This shows the finish symbol. The finish symbol illustrated here is G, which indicates that the weld will be finished by grinding.

7. This shows the tail. The tail is only used to set off symbols which indicate that you are to use a certain process or to follow certain specifications or other references; in this case you are referred to a specification numbered A-1. If there is no need to indicate the process or the specifications or other references, the tail is normally omitted from the symbol.

8. This shows the specifications, process, or other references, which is the notation explained in item 7. In this example, the tail of the symbol indicates the abbreviation of a process — oxy-acetylene welding (OAW).

RIVETING SYMBOLS

While most ship structural elements are welded, there is some riveting done—particularly in joining some portions of the superstructure. Figure 6-44 shows conventional shop and field rivet symbols. Shop rivets are those which are to be placed and driven in the shop; field rivets are placed and driven in the field. Note in figure 6-44 that you use the rivet head diameter when you draw shop rivets but that you use the rivet shank diameter when you draw field rivets.

AIRCRAFT STRUCTURAL DRAWINGS

Although aircraft drawing follows, in general, the procedures of other engineering drawing, it presents some problems rarely encountered elsewhere. Airplane drawings made by the Navy consist principally of drawings of rework, repair, and modifications to be made by the service activities for existing aircraft.

To learn the structural methods and principles applied to modern aircraft is made difficult by the fact that in aviation, design and structural methods are constantly changing.

An understanding of geometry is important, as well as skill in both orthographic and pictorial drawing and in development as applied to sheet metal work. It is often more convenient to determine measurements graphically, rather than mathematically. This requires precise measurements of the known distances and angles, care in transferring the measurements, and ability to draw smooth lines which meet accurately at points of intersection.

In addition to the drawing standards set forth in the MIL-STDs, there are usually additional standards set up by individual activities to meet their needs. When drawings are to be

made for a particular airplane, the drawing practices followed by the manufacturer of that plane will also serve as a guide.

As a general rule, detail and assembly drawings are made actual size. This necessitates the use of drawing sheets of greater width and sometimes of great length. It is desirable however, that the length should not exceed 144 inches. On large-sized drawings, horizontal and vertical zoning may be used as an aid to the location of items when the drawing is read. The approved method of zoning is described in MIL-STD-2C, Engineering Drawing Sizes and Formats.

Large detail, assembly, and installation drawings may be drawn to a reduced scale in information can be clearly shown in all respects. In order to do this, section or partial views may be drawn actual size where necessary. Draftsmen should bear in mind that the purpose of reducing the scale of a drawing is to reduce the size of the sheet to be handled and to avoid wastage of drawing and blueprint paper and file space. Therefore, as small a sheet should be used as practicable without crowding the drawing. Enough space should be left so that sectional views, notes, or tabulations can be added if these become necessary during the life of the drawing.

It is customary for every airplane part to have a number which corresponds with its detail drawing number. If more than one part is shown on one detail drawing, further identification may be accomplished by dash numbers. Thus, two parts shown on a single drawing may be numbered 34105—1 and 34105—2. On the drawing, the dash number preceeded by the dash should be placed in a small circle near the part it identifies. An arrow drawn from the circle should touch the outline of the part.

Sometimes, dash numbers are also used to distinguish between right-hand and left-hand parts which are mirror images of each other. In this case, the left-hand part may be shown and the right-hand part indicated by a note.

Draw only as many views in third-angle orthographic projection as are needed to clearly illustrate the part to be made. It is customary for principal views to be taken from the left side of the airplane with the nose pointed toward the left border of the drawing sheet. Partial views and sections may be used to illustrate certain features, thus making a greater number of complete views unnecessary.

One view may be used, for example, in drawing in a stud if the diameters are clearly marked as diameters. One view of a detail should correspond to the position of the view as shown on its next assembly drawing whenever possible. However, a part which is shown in an angular position when it is assembled should not be drawn in an angular position as a detail.

Sections should be projected directly if space permits, but if it is limited, a section view may be placed elsewhere on the sheet or on a separate sheet. Views which are not projected directly should be clearly marked to indicate the location from which they were taken and the direction in which they are viewed.

Various systems of station marking are used on aircraft drawings. For example, the center line of the airplane on one drawing may be taken as the zero station, and objects to the right or left of center along the wings or stabilizers may then be located by giving the number of inches between them and the center line zero station. On other drawings, the zero station may be at the nose of the fuselage, at a firewall, at the leading edge of a wing, or at some other location, depending on the purpose of the drawing and the custom concerning the particular part or assembly. (See fig. 6-45.)

Isometric, perspective, or orthographic views may be employed under some conditions where one of these types of drawing more clearly depict the article than the conventional ortographic projection. These drawings are of particular advantage when it is necessary to illustrate the installation of plumbing, wiring, or control linkage. However, with the curving lines and lack of parallelism, aircraft drawing is not considered easy even in orthographic projection, and the problems can be greatly magnified when an attempt is made to work in three dimensions. When three-dimensional drawings must be made, time can be saved and the work made easier if portions of new drawings, especially outlines, can be traced from other drawings and the appropriate additions drawn in. (See fig. 6-46.) A file of isometric outline drawings may be kept in the drafting room for this purpose.

Because of the large size of many drawings, dimensions should be made to read from the bottom. Dimensions are usually given in inches although some over-all dimensions, such as

Figure 12-22.—Basic configuration of the parametric amplifier.

because it is sensitive to source impedance changes. The operation of the one-port difference-frequency parametric amplifier for the achievement of low-noise amplification (fig. 12-23) is as follows:

The varactor D (variable-capacitance diode) must couple together all the resonant sections at three frequencies—signal, idler, and pump. For amplification to occur, the sum of the idler and signal frequencies must equal the frequency of the pump. The signal frequency must be much lower than the idler frequency to achieve low noise. However, due to the imperfect nature of the varactor, there is an upper limit for the idler frequency at which noise will increase. The capacitance of the varactor will be varied at the pump frequency rate by power from the pump. Some of this power is transferred and added to the signal when the two frequencies are mixed, resulting in power amplification. The output signal is then taken from the circulator, which separates the input and output signals.

MODULATING OSCILLATORS

Oscillators are an indespensable part of most electronic equipments. However, in order to make the most use of the oscillator, it is necessary to insert some form of signal waveform that is used to convey information, messages, timing data, or whatever intelligence must be transferred from the transmitter to the receiver. Without this added information, the oscillator would in most cases be of no value.

Figure 6-47.—Airplane nomenclature.

Figure 6-48.—Semimonocoque fuselage.

(B) Two-spar wing construction with web support.
(C) Detail of a spar.

wing span, are sometimes given in feet. In many activities, it is preferred that all dimensions be given in decimals instead of in common fractions.

A study of figure 6-47 will serve to refresh your memory with the names of the important parts of a typical airplane. The main structural unit is the fuselage, and other units are attached directly or indirectly to it.

Most military aircraft have what is known as semimonocoque construction. In this type, part of the stress is borne by the shell and part by lengthwise members, called stringers. (See fig. 6-48.)

Typical wing structures are illustrated in figure 6-49. Illustrated in figure 6-49A is a pictorial drawing showing the construction of a two-spar aircraft wing, using struts to brace the upper and lower chords of the rib. Figure 6—49B illustrates another two-spar wing construction using a web with lightening holes, (to decrease the weight) to support the upper and lower chords of the rib. Figure 6-49C is a detail drawing of a spar construction.

CHAPTER 7

MECHANICAL AND ELECTRICAL DRAWINGS

Mechanical and electrical drawings relate primarily to various kinds of systems; plumbing systems, ventilating systems, power systems, and so on. The basic MIL-STDs 1B, 2C, and 7A apply to these drawings as well as to the machine and structural drawings described in chapter 6. However, mechanical and electrical drawings are generally more schematic and diagrammatic than machine and structural drawings. A typical machine drawing shows every detail of the object depicted, but mechanical and electrical drawings may show only symbols which represent fittings, fixtures, or a complex item of machinery. Machine drawings are drawn carefully to scale; some mechanical and electrical drawings may not be drawn to any scale at all.

As was explained in chapter 6, the ship drawings, including the mechanical and electrical systems shown thereon, will have been prepared under the direction of BuShips. Any extensive revisions to the drawings will be made by shipyard or BuShips personnel. However, as with machinery or structural changes or repairs, it is possible that minor modifications to or extensions of mechanical and electrical systems may require that drawings be prepared locally. The draftsman who makes revisions to the ships drawings should know enough about the various mechanical and electrical systems so that he can distinguish one from another on the plans and be able to follow verbal instructions relating to the revisions. He should also have some knowledge of piping, cable, fittings fixtures, and appurtenances so that he can indicate the correct material designations and select the appropriate standard symbols for the drawings.

MECHANICAL DRAWINGS

As used here, mechanical drawings include the drawings of all kinds of piping and ductwork systems. Aboard ship, these systems include steam, water, air, fuel, ventilation, drainage, and other distribution and collection networks described in the following sections.

SHIPBOARD PIPING SYSTEMS

There are literally dozens of different categories of piping systems aboard ship. Since there may be a number of independent systems of one category, a count aboard a large ship would reveal scores of separate piping systems consisting of miles of piping. Some of these systems are identified in the following paragraphs. Each piping system consists of sections of pipe or tubing, fittings for joining the sections, and valves for controlling the flow of fluid. Most piping systems also include a number of other fittings and accessories such as vents, drains, traps, strainers, relief valves, and gages and instruments. Some of the following brief descriptions include a mention of various items of machinery or equipment related to or served by the system. On mechanical drawings, these items of equipment may be shown by a symbol, a block containing an abbreviation or words to identify the item, a rather symbolic outline conforming to the general shape of the item, or a pictorial representation of the item. Which of these methods of indicating machinery and equipment is to be used on a specific drawing depends on the scale and purpose of the drawing. The following descriptions also mention some of the materials of which the piping is made. This is generally indicated on the drawing in a material block, but it may also be shown adjacent to the line representing the pipe. Further, the type of material of which the pipe is made is closely related to the types of joints or connections used; and the type of connection (screwed, welded, soldered, and so on) is frequently shown on a mechanical drawing at each fitting and connection.

STEAM SYSTEMS

The main steam system is a comparatively short system but a very important one. Steam is generated in the boiler, then routed to the propulsion turbines, to the turbogenerators, and to the soot blowers via lines that are made of alloy steel tubing.

Auxiliary steam systems are either high pressure or low pressure, depending upon the units which they serve. The high pressure auxiliary steam system serves fire and bilge pumps, various service pumps, and fuel oil heaters. The piping and tubing is of the same material as that used in the main steam system. The low pressure auxiliary steam system is used for steam heat and for air ejectors in the distilling plant; seamless steel or copper pipe or tubing is used. The auxiliary steam system is routed in the form of a loop, with cross connection at suitable intervals; branch lines serve the various units of auxiliary machinery.

Service steam systems are low pressure systems which serve compartment heating units, galley equipment, fresh water heaters, and laundry equipment. Service steam systems are either constant service or intermittent service systems. Constant service systems are those in use the year around. Intermittent service steam systems are for heating services not required except in cold weather. Constant and intermittent service lines are usually cross connected.

WATER AND DRAINAGE SYSTEMS

Generally speaking, there are two classes of water: fresh water and sea water. The term fresh water is used on board ship to refer to potable water, feed water, reserve potable water, and reserve feed water. Potable water is water known to be of drinking water quality, while feed water is water known to be suitable for use in the ship's boilers.

Feed Water System

The condensate system and the boiler feed system, together, are frequently referred to as the feed water system.

The condensate system includes all the apparatus and piping used to collect and condense steam. The condensate system includes the main and auxiliary condensers, a pump or a combination of pumps, and the piping required to carry the condensate from the condenser to the deaerating feed tank. The main and auxiliary condensers recover feed water by condensing exhaust steam from propulsion turbines, generator turbines, and various auxiliary machinery units.

The boiler feed water system includes the deaerating feed tank, the feed booster pump, the main feed pump, and the piping required to carry the feed water from the deaerating feed tank to the boilers.

Steam and Fresh Water Drains

Most of the feed water in a shipboard steam plant is recovered so that it can be used over and over again for the generation of steam. As steam is condensed in the main and auxiliary condensers, the condensate is returned to the feed system. Also, the steam exhausted from auxiliary machinery is collected in the auxiliary exhaust system and is returned to the feed system. But steam is used throughout the ship in a good deal of machinery, equipment, and piping which does not exhaust either to a condenser or to the auxiliary exhaust system. Therefore, steam and fresh water drain systems are provided so that water can be recovered and put back into the feed system after it has been used (as steam) in fuel oil heaters, distilling plants, steam catapult systems, water heaters, whistles and sirens, and many other units and systems throughout the ship. The systems of piping which carry the water to the feed system, and also the water carried in the system, are known as drains.

There are five steam and fresh water drain systems on ships built to Navy specifications: (1) high pressure drainage systems, (2) service steam drainage systems, (3) oil heating drainage systems, (4) fresh water drain collecting systems, and (5) contaminated drainage systems. Most drain lines are fitted with steam traps to keep steam from passing into the drain systems.

High pressure drains generally include drains from superheater headers throttle valves, main and auxiliary steam lines, steam catapults (on carriers), and other steam equipment or systems which operate at 150 psi or above. High pressure drains are returned to the feed system by way of the deaerating feed tank.

The service steam drainage system collects drains from low pressure (below 150 psi) steam piping systems and steam equipment outside of

10002

:0001!

the machinery spaces. On some ships, these drains discharge into the most convenient fresh water drain collecting tank; on other ships, particularly on large combatant ships such as carriers, the service steam drains discharge to two special service steam drain collecting tanks located in the machinery spaces—one in a forward machinery space, and one in an after machinery space. The drains are returned from the service steam drain collecting tanks to the feed system.

The oil heating drainage system collects drains from the steam side of fuel oil heaters, fuel oil tank heating coils, lubricating oil heaters, and other steam equipment that is used to heat oil. Since leakage in the heating equipment could cause oil contamination of the drains, these drains are collected separately and inspected before they are discharged to the feed system.

The fresh water drain collecting system (sometimes called the low pressure drain system) collects drainage from various piping systems, machinery, and equipment which operate at steam pressures of less than 150 psi.

Fresh water drains are collected in fresh water drain collecting tanks located in the machinery spaces. The contents of these tanks are discharged to the feed system.

A contaminated drainage system is installed in each main and auxiliary machinery space where dry bilges must be maintained. It collects oil and water from machinery and piping which normally has some leakage, and drainage from any other services which may at times be contaminated. The contaminated drains are collected in a bilge sump tank located in the same machinery space. The contents of the bilge sump tank are removed by the bilge drainage system.

Fresh Water Systems

Practically all fresh water used aboard ship is made by boiling sea water in the evaporators and condensing the resulting vapor. Water for general use is stored in peak tanks, or in other tanks at a distance from the machinery spaces; water intended for boiler use is stored in feed tanks located in the double bottoms or in wing tanks adjacent to the machinery spaces.

In the system which supplies hot and cold fresh water to scuttlebutts, sinks, showers, scullery, and galley, normal operating pressure is from 35 to 50 psi. This pressure is maintained by automatic electric pumps which take suction on the storage tank and discharge to fresh water pressure tanks.

Electronics Cooling Water System

Cooling water systems are now provided on most ships to cool electronics equipment. In this system, fresh water is usually circulated through the electronics equipment to carry away the heat generated during operation.

Firemain System

The firemain system aboard naval ships is a system of piping that receives water pumped from the sea and delivers it to fireplugs and sprinkler systems. It has certain additional functions, such as supplying water to flushing systems and supplying cooling water to auxiliary machinery; in certain installations it serves other purposes as well.

The type of firemain system installed on naval ships is governed by the physical characteristics and functions of each ship. The firemain may be a single main, a horizontal loop, or a vertical loop system.

Regardless of the type, the whole firemain system is so designed that a damaged section can be isolated, thus preventing loss of pressure in the remainder of the system.

In ships built to Navy specifications, the firemain material is required to be copper-nickel alloy with copper-nickel or bronze fittings and bronze valves. There are, however, a number of older ships that have the firemain system constructed of ferrous material.

Sprinkling Systems

Sprinkling systems are installed aboard ship in magazines, turret handling rooms, hangar decks, missile spaces, and other spaces where flammable materials are stowed. Water for these systems is supplied from the firemain through branch lines.

Most sprinkling systems aboard ship are of the dry type—that is, they are not charged with water beyond the sprinkling control valves except when they are in use. Sprinkling systems in magazines which contain missiles are of the wet type. The sprinkling control valves in magazine sprinkling systems are operated automatically by heat-actuated devices. Other sprinkling control valves are operated manually or hydraulically, either locally or from remote

10003

stations. In those areas of the ship in which major flammable liquid fires could occur, such as in aircraft hangars, foam sprinkling systems are provided.

Piping material used in sprinkling systems is copper-nickel.

Washdown Systems

Washdown systems are installed aboard ship for the purpose of removing radioactive contamination from topside surfaces of a ship.

Essentially, the washdown system is a dry-pipe sprinkler system, with nozzles specially designed and installed so that they will throw a large spray pattern on all weather decks.

Flushing System

The flushing system is supplied with sea water by a branch from the firemain or by a separate sanitary and flushing pump taking suction from the sea. When this system is supplied from the firemain, the branch is taken as near the top portion of the main as possible so that sediment from the firemain will not enter the flushing system. Since the firemain pressure is too high for a flushing system, the water is led through a strainer to a reducing valve which reduces the pressure to 35 psi.

Waste Drainage Systems

The drainage system aboard ship is divided into two parts: the main and secondary systems, which pump waste from the bilges and other spaces, and the plumbing and deck drains. Between them, these systems collect and dispose overboard all the shipboard waste fluids.

The main drainage system consists of piping installed low in the ship, with suction branches to spaces to be drained and direct connections to eductors or drainage pumps. This system generally serves the main machinery spaces and a few other spaces.

The secondary drainage systems supplement the main drainage system wherever the main drainage system cannot be extended because of interference of spaces through which the passage of piping is prohibited, or because the length of piping would be too great for efficient drainage. Each secondary drainage system is independent of the main drainage system and has its own pumps or eductors and its own sea connections.

Plumbing and deck drains are divided into two classes—A and B. Drains from water closets, urinals, and sick bay fixtures are class A drains; all other plumbing drains are class B.

Since shipboard flushing systems use salt water, the class A drainage piping is usually copper-nickel alloy. Class B drains are made up of brass or copper.

FUEL OIL SYSTEMS

The fuel oil system is arranged so as to allow the transfer of fuel oil from fueling connections to storage tanks, from storage tanks to service tanks, and from service tanks to the burners at the boiler. It also allows the transfer of fuel oil from one storage tank to another; these transfers are made with pumps, manifolds, and sometimes sluice valves which permit gravity flow from one storage tank to another.

The filling and transfer system usually consists of two large lines, one on each side of the ship, running fore and aft. Cross-connections join these mains to the fuel oil booster and transfer pumps. Risers are provided fore and aft for taking on or delivering fuel.

DIESEL OIL AND JP-5 SYSTEMS

Diesel oil systems are found even on steam-driven ships. Ships that carry large supplies of diesel oil have fairly complex diesel oil systems which are quite similar to the boiler fuel oil systems already described.

On aircraft carriers, JP-5 aviation fuel can also be used as boiler fuel in case of emergency. The JP-5 system is separate from the boiler fuel oil system but can be connected so as to discharge JP-5 to the fuel oil service system.

LUBRICATING OIL SYSTEMS

The lubricating oil system serves to supply clean, cool oil to machinery bearing surfaces. Lube oil is routed from the filling connection to the storage or sump tank located beneath the engine room; from this tank it is pumped through a series of strainers, coolers, and meters to the bearing surfaces. Used oil is routed to a settling tank, then through purifiers, and back to the sump tank.

10008

HYDRAULIC SYSTEMS

Hydraulic systems operate remote control valves for flooding, counterflooding, and ballasting. Other examples of the transmission of power aboard ship by hydraulics are the operation of steering gear, small hydraulic presses in the shop, and hydraulically operated pipe benders.

COMPRESSED AIR SYSTEMS

Compressed air systems are fabricated from brass and copper piping materials, bronze silver-brazed fittings, and bronze valves. Moisture and oil must be kept out of compressed air systems. Oil and moisture separation filters and air dryers are provided to remove these contaminating substances from the system.

The high pressure air system is designed to provide air for services such as counterrecoil, diesel engine starting, gas ejection, torpedo charging, and torpedo workshops.

The ship's service air system is a low presure compressed air system installed on practically all surface ships. The ship's service air system supplies air at required pressures for the operation of pneumatic tools, the operation of oil-burning forges and furnaces, the charging of pump air chambers, the cleaning of equipment, and many other uses.

Gas ejecting systems, where required, are provided for supplying air at the required pressure to the breeches of guns for removing gases and unburned solid matter.

A starting and control air system for diesel engines is installed on each vessel that requires air for diesel engine starting and the control of equipment such as clutches, engine selector valves, turning gear, and propeller brake.

A compressed air system is installed on some steam-driven ships to provide air for the automatic combustion control system on the boilers.

REFRIGERATION SYSTEMS

Mechanical cooling is provided in submarines and very often in certain spaces on surface ships where it is of importance for the comfort, health, and alertness of personnel or for the preservation of equipment.

The principal components of the system are the compressor, the condenser, the receiver, and the cooling coils (evaporator). Additional equipment required to complete the system includes piping, pressure gages, thermometers, various types of control switches and control valves, strainers, relief valves, sight-flow indicators, dehydrators, and charging connections.

PIPING AND TUBING

The Bureau of Ships defines piping as an assembly of pipe or tubing, valves, fittings, and related components forming a whole or a part of a system for transferring fluids (liquids and gases).

It is a little harder to define pipe and tubing. In commercial usage, there is not clear distinction between pipe and tubing, since the correct designation for each tubular product is established by the manufacturer. If the manufacturer calls a product pipe, it is pipe; if he calls it tubing, it is tubing.

In the Navy, however, a distinction is made between pipe and tubing. This distinction is based on the way the tubular product is identified as to size.

Figure 7-1.—Wall thickness designations.

There are three important dimensions of any tubular product: outside diameter (OD), inside diameter (ID), and wall thickness. A tubular product is called tubing if its size is identified by actual measured outside diameter (OD) and by actual measured wall thickness. A tubular product is called pipe if its size is identified by a nominal dimension called iron pipe size (IPS) and by reference to a wall thickness schedule designation.

Pipe is sometimes identified as standard (Std), extra strong (XS), or double extra strong (XXS), according to wall thickness. Figure 7-1 shows the relative wall thicknesses of pipes having the same nominal (OD) pipe size. As you can see, the inside diameter is reduced as the wall thickness is increased.

The terms standard, extra strong, and double extra strong do not identify any one actual wall

Figure 7-2.—Typical pipe fittings.

10006

Figure 7-3.—Flanges.

10007

thickness of pipe. For example, a 3-inch OD pipe would be designated as double extra strong if it has a wall thickness of 0.600 inch, while a 4-inch OD pipe would be designated as double extra strong if it has a wall thickness of 0.674 inch.

Since pipe is manufactured in a number of different sizes, some pipe does not fit into the standard, extra strong, or double extra strong designations. The wall thickness of such pipe may be stated in decimal parts of an inch (as 0.120 inch wall) or it may be designated by reference to schedule numbers established by the American Standards Association (ASA). For example, a reference to "Schedule 40" for a pipe of 3-inch OD would indicate a wall thickness of 0.216 inch. The wall thickness of a schedule 40 pipe of 4-inch OD is 0.237 inch. These and many other values can be found in pipe tables in most engineering handbooks.

Some of the descriptions of piping systems in the previous section of this chapter included a mention of the pipe materials. The following paragraphs describe the piping and tubing used most frequently aboard ship.

Seamless steel pipe is available in standard and extra strong wall thicknesses in lengths from 12 to 22 feet. Seamless steel pipe is used aboard ship for diesel exhaust systems, overflow lines, sounding tubes, vents and air intake systems.

Welded steel pipe, either galvanized or ungalvanized (black), is available in standard and extra strong wall thicknesses.

Welded steel pipe is used primarily for general service such as plumbing drain lines aboard ship.

Seamless steel tubing is used in oil, steam, and water lines operating at 775° F and below. Different types of this tubing are available for use, according to the working pressure that will be maintained in the lines.

Welded steel tubing is available in two types, for use as follows:

Type A is used in steam or oil lines where maximum working pressure is 150 psi and in water or gas lines operating at a maximum working pressure of 225 psi.

Type B is used in steam lines operating at a maximum working pressure of 300 psi; in oil lines operating at a maximum working pressure of 350 psi; and in water or gas lines operating at a maximum working pressure of 400 psi.

Seamless chromium-molybdenum alloy steel tubing is used in high pressure steam lines at working pressures of 1201 to 1500 psi and operating temperatures of 1000° F. This tubing is furnished in lengths of 12 to 24 feet.

Several types of seamless aluminum alloy tubing are available. Tubing made of aluminum alloy 6061 is used primarily for dry lines in magazine sprinkling systems and for some structural applications. Tubing made of aluminum alloy 5052 is used for bilge and sanitary drain systems.

Seamless brass tubing (semiannealed and light annealed) is available in types and sizes suitable for operating pressures ranging from 200 psi to 4000 psi. It is used in systems which must resist the corrosive action of salt water, fresh water, or other fluids; it is a possible substitute for copper tubing aboard ship. Seamless hard drawn brass tubing is used for voice and pneumatic tube installations.

Seamless copper tubing suitable for pressures up to 6000 psi is covered by specification MIL-T-873. This material is intended for general use aboard ship; when not threaded, it may be joined by flanged joints, soldered joints, or flared fittings. Other types of copper tubing are available for refrigeration installations, plumbing and heating systems, gasoline systems, lubrication systems, and other shipboard uses.

Copper alloy tubing is available in composition 70-30 (70 percent copper and 30 percent nickel) and in composition 90-10 (90 percent copper and 10 percent nickel). Both seamless tubing and welded tubing are available in each composition. The 70-30 composition has been used for some time in shipboard piping systems and heat exchangers.

Every shipboard piping system includes a variety of fittings made from a number of different metals and alloys, and available in the same size range as the pipe and tubing used in the systems. Some typical fittings are shown in figure 7-2. In addition to illustrating some of the different shapes of fittings, this figure also indicates various methods of making connections: screwing, welding, and brazing. Pipes and fittings are also connected by means of flanges (see fig. 7-3). Flanges can be attached to pipes and tubing by welding, brazing, rolling, flaring, or (in some low pressure systems) with screw threads.

Every piping system must have some means of controlling the amount and direction of the flow of liquid or gas through the lines. This is

Figure 12-23.—One-port difference-frequency parametric amplifier.

The process of injection this intelligence into the oscillator frequency is called MODULATION. There are many types of modulation employed in airborne electronics—amplitude, frequency, phase, pulse, single-sideband, etc. The major part of this portion of the chapter will be devoted to the pulse modulation techniques most often employed in radar systems.

PULSING TRIODE OSCILLATORS

Basically, there are two methods of pulsing UHF and microwave oscillators. Operation of normal oscillators is discussed fully in chapter 8 of Basic Electronics, NavPers 10087-B. A thorough review of the basic principles of oscillators at this time may prove valuable for the understanding of the following discussions of the methods of modulating oscillators.

The first method to be discussed is that used in the self-pulsing oscillator, which contains within itself the circuitry needed to permit oscillation for a period of time, and to quench oscillation periodically. This ON-OFF action results in pulses of energy in the form of radiofrequency oscillations for a period of time, followed by no oscillation.

The second important method of modulating UHF and microwave oscillators incorporates the use of separate modulator circuits to trigger the oscillator into its ON-OFF states of operation.

Self-Pulsing Oscillators

Most oscillators use grid leak bias or a combination of grid leak and fixed bias. One advantage of grid leak bias is that the amplitude of oscillation is limited and stabilized. Notice the graphs of plate current and grid voltage versus time in figure 12-24 (A). These waveshapes are essentially the same for all oscillators using grid leak bias.

At zero time, plate voltage is applied but the grids are grounded so that a steady plate current flows. At time t_1 the ground is removed, and any random change in plate current will cause a change in voltage in the plate tank circuit, a portion of which is fed back to the grid circuit. Since this feedback is in the right phase and amplitude, the oscillations will grow in amplitude. Each time the grid goes positive, grid current flows and charges the grid leak capacitor more negatively so that on each successive oscillation the average grid voltage (the bias) goes more negative.

This continues until a balance is reached, and just enough grid current is drawn to replace the charge which leaks off through the grid leak resistor during the remainder of the cycle. As the average grid voltage becomes more negative, the plate current flows for a shorter portion of each cycle until the flow is just sufficient to replace the energy lost in the tank circuit and to supply feedback to the grid circuit.

998

accomplished by the installation of valves, which can be opened or closed as required.

Valves are usually made of bronze, brass, cast or malleable iron, or steel. Steel valves are either cast or forged, and are made of either plain steel or alloy steel.

Many different types of valves are used to control the flow of liquids and gases. There are two main groups of valves. Stop valves are those which are used to shut off (or, in some cases, to partially shut off) the flow of fluid; these valves are controlled entirely by the movement of the valve stem. Check valves are used to permit the flow of fluid in only one direction; these valves are controlled by the movement of the fluid itself.

Valve designs vary greatly, due to the varying demands of service. You will find some valves which are combinations of the more or less basic types just mentioned; and others (such as reducing valves) which must be considered as special valves, bearing only slight resemblance to the basic types. Typical valves are shown in figure 7-4.

Traps are used to remove various undesirable materials from piping systems. In air lines, a trap is installed to remove water which is usually present. In steam lines, traps are

Figure 7-4.—Globe and gate valves.

10009

Figure 7-5.—Typical shipboard refrigerant circulating air conditioning system.

installed to remove condensate. Essentially, any steam trap consists of a valve and some device or arrangement which will cause the valve to open and close, as necessary to drain condensate from the lines without allowing the escape of steam.

Strainers are located in all piping lines to prevent the passage of foreign matter. In some locations, duplex strainers are used so that the flow of fluid through the system need not be interrupted when one element is removed for cleaning.

PIPING DRAWINGS

As we stated at the beginning of this chapter, the method of drawing piping, fittings and equipment depends on the scale and purpose of the drawing. Some drawings used in operation and maintenance manuals are quite pictorial—each fitting and item of equipment may be drawn in some detail. Figure 7-5 is an example of this kind of drawing.

Most piping drawings, however, are more schematic. Figure 7-6, which is taken from MIL-STD-7A, is a typical piping diagram. Note the use of symbols, notes, and a parts list.

Military Standard Mechanical Symbols, Part 1, MIL-STD-17B-1, establishes an approved list of mechanical symbols. These symbols have been adopted, by permission of the American Standards Association and the American Society of Mechanical Engineers, from various American Standards. Some of these symbols are shown in figure 7-7. Note that symbols may indicate types of connections (screwed, flanged, welded, and so on) as well as various fittings, valves, gages, and items of equipment. When a symbol is needed for an item not covered in the standards, a suitable symbol should be designed by the activity concerned. A new symbol should not duplicate any symbol in the standards, should be clearly understandable, and should be explained by a note on the drawing.

Figure 7-8 shows a few of the many pipe line symbols set forth in MIL-STD-17B-1. Since one drawing may contain a number of separate piping systems of the same kind, additional letter symbols should be added to differentiate the separate networks.

MIL-STD-17B-1 permits, in lieu of the types of symbols shown in figures 7-7 and 7-8, the use of special fluid power diagram symbols. Figure 7-9 shows typical symbols of this type. Component symbols can be devised for any fluid power component by combining basic symbols. Notes regarding pressure, flow rate settings, and other characteristics are added to the symbols when they are used to make up a fluid circuit diagram.

Figure 7-10 shows a typical drawing which makes use of the basic symbols shown in figure 7-7. Note that the drawing includes a legend. MIL-STD-17B-1 requires that each drawing or one sheet of each set of drawings show a legend. But then MIL-STD-17B-1 goes on to state that reference to the MIL-STD or American Standards may be used in lieu of a legend. In spite of this, a legend should be used whenever possible because it is of great assistance to anyone who is not completely familiar with the symbols.

Since symbolic representation does not usually involve exact or scale layout or the actual run or leads of piping, the same symbol should be used for all projections of the system (plan, elevations, and sections).

Some piping diagrams, particularly those at a small scale, do not include symbols for fittings and types of connections.

On those drawings where symbols for pipe fittings are not used in the diagrammatic representations, the intersection of any two piping runs is represented by showing the pipe symbols in contact. (See fig. 7-11.)

Cross-overs where there is no connection between piping runs are represented by a break in one of the lines. (See fig. 7-12.)

Not all of the piping drawings which you may draw or revise will make use of the MIL-STD-17B-1 symbols. A typical example of these exceptions is shown in figures 7-13 and 7-14. Note that there are some small differences between the symbols in figure 7-13 and the legend in figure 7-14. This, again, emphasizes the importance of the inclusion of a legend on piping drawings.

SHIPBOARD VENTILATION

The main difference between the ventilation systems of ships and the hot air heating systems which are popular in houses is the watertight and airtight construction of the ducts on a ship. Also, shipboard equipment will, in many cases, be of sturdier and more costly construction, since its proper functioning and reliability are of vital importance.

To preserve the watertight integrity of a vessel, shipboard ventilation is divided into many small systems. Some of these systems are for supply and others for exhaust. Figure 7-15 shows the general characteristics of one supply system and one exhaust system.

A supply ventilation system is designed to serve a group of compartments and spaces with an adequate amount of fresh air. The air enters the system through some type of waterproof ventilation intake located on or above the main deck or in a deckhouse bulkhead. From the intake, the air for the lower deck compartments ordinarily passes through a vertical duct, known as a trunk, which is usually built as part of the ship's structure. An air preheater with a con-

Figure 7-18.—Action of air currents in turns.

Figure 7-19.—Concentric reducer with takeoff.

trolling thermostat is placed as near as is practical to the intake end of the system.

A fan provides the suction to pull the air into the intake and down the trunk. The fan may be of either the centrifugal type or the axial flow type. Note the differences shown in figure 7-16.

In an intake system serving a large number of compartments, the air leaving the fan goes first through a main, then through branch mains, and finally through smaller branches. Reheaters are located in the branch mains or smaller branches to serve a group of individual spaces or compartments. At the end of the line, air is delivered through end openings known as supply terminals. In some types of terminals, dampers are installed which can be manually operated.

Ordinarily one exhaust system serves the same spaces and compartments that are served by one supply system. Axial flow fans are never used in exhaust systems if the air might contain flammable or explosive vapors or fumes.

Ductwork

In designing ventilation ducts, watertight integrity of compartments and spaces served by the ventilation system must be maintained. Watertight integrity is particularly important for branches which extend to lower decks and platforms. Penetration of watertight and armored decks and bulkheads is avoided whenever possible. When ducts must pass through such boundaries, they must be watertight with specified closures and fittings of welded construction.

In order for air to move through ducts efficiently with minimum friction loss from seams, joints, turns, and fittings, the interior of ducts must be streamlined. Also, in order that excessive noise be avoided, seams, splitters, dampers, vanes, and terminals should be carefully designed so that air can flow quietly over and around them.

Duct sections are ordinarily made of galvanized steel, unless some other material, such as aluminum or corrosion-resisting steel, is specified.

Welded seams are preferred for watertight ducts. Round ducts made of heavy metal are sometimes lapped at the seams and riveted with tinner's rivets. The lapped surfaces are tinned before riveting and then sweated together after riveting.

Stiffeners are used to minimize vibration of the walls of large rectangular ducts. They are usually made of lightweight angle bars and riveted to the outside of the ducts, as shown in figure 7-17. No stiffeners of any kind are to be placed inside a duct.

Turns in air ducts should be as few and as far between as it is practicable to make them. Formerly most turns were of the elbow type, also called radius turns, for both round and rectangular ducts. Now the trend is toward vaned turns. Figure 7-18 shows the action of moving air in the two types of turns.

Ordinarily when a branch takes off from a main, the size of the main is reduced where it extends past the takeoff. The reducer connecting the two sections is the proper place to locate the takeoff. A concentric reducer, with a takeoff, is illustrated in figure 7-19. It is used with either supply or exhaust systems.

With appropriate vaned turns, the branch main can be taken off at various angles. The branch main shown in figure 7-20 is taken off at an angle of 90 degrees. Notice the SPLITTER. It proportions the amount of air directed into the branch main. The splitter is usually made so that it is adjustable, but after its correct location is determined, it is riveted in place.

Small round branches are sometimes taken off branch mains, as illustrated in figure 7-21. Notice the SCOOP, which can be used to feed air into the branch.

Ducts passing through armored decks require special installations. Watertight ducts which are 8 inches or less in diameter pass through round holes and are welded to the deck. A duct more than 8 inches in diameter is connected to a venturi tube, provided the hole for the tube does not exceed 8 inches in diameter or that the velocity of the air will not exceed 10,000 feet per minute. Figure 7-22 illustrates an elbow-type venturi tube.

Living-space supply terminals are ordinarily installed in a vertical position. The open end of the terminal is usually located between 9 and 18 inches from the deck in berthing spaces and below the lowest bunk. The cone-shaped outlet is designed to lessen the velocity of the air that is discharged into the space.

Supply terminals for magazines, handling rooms, and staterooms are located in a horizontal position near the overhead. The design of various terminals is shown in figure 7-23.

Adjustable supply terminals are used in hot spaces, such as engine and machinery rooms, radio and sound rooms, workshops, laundries, and turrets. Adjustable slip sections provide a

Figure 7-27.—Simple circuit.

00023

means of controlling air direction. (See fig. 7-24.) Air can thus be discharged directly in the vicinity of most of the personnel.

Navy standard diffusing terminals are used in offices, staterooms, wardrooms, mess rooms, and in spaces which have air conditioning. A standard diffusing terminal is installed in a duct as shown in figure 7-25.

Access plates are placed in ducts to provide an easy means of inspection and to facilitate assembly and cleaning. An access plate is ordinarily round and is closed with a cover plate. A collar is fitted to the opening in the duct and flush riveted into place.

Ducts are covered with insulating material whenever it is necessary to prevent condensation or objectionable gain or loss of heat. Ventilation heaters are insulated to keep in the heat and to protect personnel from burns.

Symbols for Drawings

The general information given previously concerning piping drawings applies also to ventilation drawings. Again, MIL-STD-17B-1 provides standard symbols for the drawings. Figure 7-26 shows some typical ductwork symbols from MIL-STD-17B-1.

ELECTRICAL DRAWINGS

As used here, electrical drawings includes the drawings relating to shipboard electrical wiring systems. In addition to various power distribution systems, the electrical wiring networks aboard ship include announcing and intercommunicating systems, alarm and warning systems, ship control order systems, and many others.

ELECTRICITY

Electric current consists of a flow of electrons along a conductor, usually copper wire. The flow is very similar to the flow of water in a pipe. Metallic atoms give up the electrons to other atoms very easily. Since electric current, according to theory, consists of a flow of electrons from atom to atom, metals make good conductors of current.

Some materials, unlike metals, require a very great force before electrons can be detached from their atoms. These materials are good insulators and are used to insulate conductors so that the electric current flowing in them is kept within bounds.

In its simplest form, an electrical circuit consists of the power source, which may be a battery or generator, the load, which is the device which consumes the electrical power and transforms it into useful work, and the conductor carrying current from the source to the load and from the load to the source. (See fig. 7-27.)

Electric current flows out of the negative terminal, around the circuit through the load, returning to the positive terminal at the source.

The generator or battery furnishes the electrical force which appears as a difference in potential across the positive and negative terminals of the circuit. This difference in potential between the two terminals is called the source voltage. So long as the circuit is unbroken and the battery or generator is functioning, electrons will flow from the negative terminal through the load and return to the positive terminal.

Direct current (d-c) flows through a circuit in one direction only. It may be a constant or a pulsating d-c, but the direction of flow never changes. Alternating current (a-c), which is the current commonly used in power circuits, especially for long distance transmission, flows first in one direction through a circuit and then is reversed, flowing in the opposite direction.

Constant direct current builds up to a peak of current flow for a given load and maintains that peak. Pulsating d-c rises and falls, as its name indicates. Alternating current rises and falls in one direction; then reverses and rises and falls in the other direction. The specified cycles of an alternating current mean the number of times this happens in 1 second. For example, 60 cycle current means there are 60 cycles to a second.

The rate of current flow in a circuit is measured in amperes. The amount of current flowing in a circuit depends on two things: (1) electromotive force (voltage or potential difference) and (2) resistance.

Resistance is measured in ohms. The resistance of a conductor depends upon a number of things. Of first importance is the material of which it is made. If a conductor is made of a material composed of atoms which lose their electrons very easily, it will provide less resistance to current than if its atoms require more force before their electrons are detached. Also, the diameter of the conductor is important. Like a pipe carrying water, it offers less resistance to current if its diameter is large than

it does if its diameter is small. A third factor in resistance is the length of the conductor. The longer the conductor, the greater will be its resistance. A fourth factor is temperature. The resistance of most material increases slightly with a rising temperature; the resistance of some remains about the same; and that of some decreases with a temperature rise.

The potential difference across the input terminals of a circuit is supplied by the electromotive force (emf) of the generator or battery. This electric force is measured in VOLTS. It takes one volt to establish a current flow of one ampere in a circuit possessing a resistance of one ohm. This is a statement of Ohm's law. Expressed as a formula, $E = IR$, with E standing for emf in volts, I standing for current in amperes, and R for resistance in ohms. As you will notice, this formula can also be written

$$I = \frac{E}{R} \text{ or } R = \frac{E}{I}$$

Thus if two factors of Ohm's law are known, the other is easily computed.

Power may be defined as "work per time." There is a constant relationship between the electromotive force (E), the current (I), and the power consumption (P) in a circuit. This relationship is expressed in the formula $P = IE$, from which it follows that $I = \frac{P}{E}$, and $E = \frac{P}{I}$. P is measured in units called "watts", a watt being defined as the work done in 1 second when 1 ampere flows under an electromotive force of 1 volt.

Suppose, now, that you have a 110-volt circuit in your home. The constant E of this circuit, then, is 110-volts. In the circuit there is probably a 15-ampere "fuse." This is a device which will open the circuit (usually by "burning out") if the current in the circuit exceeds 15 amperes. The reason for the existence of the fuse is the fact that the wiring in the circuit is designed to stand safely a maximum current of 15 amperes. A current in excess of this amount would cause the wiring to become red-hot, eventually to "burn out," and perhaps to start an electrical fire.

Suppose you light a 60-watt bulb on this circit. Your E is 110 volts. By the formula $I = \frac{P}{E}$, you know that the current in the circuit with the 60-watt bulb on is $\frac{60}{110}$, or about 0.54 amperes, which is well within the margin of safety of 15 amperes.

But suppose now that you cut in on the same circuit an electric toaster taking about 1500 watts (electrical devices are usually marked with the number of watts they consume) and an electric clothes dryer taking about 1200 watts. The total P is now 60 + 1500 + 1200, or 2760 watts. The current will now be $\frac{2760}{110}$, or 25 amperes. Theoretically, of course; because before it reaches this point the 15-ampere fuse will burn out and open the circuit.

The "work per time" definition of power can be applied to mechanical power as well as to electrical power. Work may be defined as a force acting through a distance and expressed: work = force x distance. If you lift a 30-pound weight a distance of 2 feet, the work you have done may be expressed thus: work = 30 pounds x 2 feet = 60 foot-pounds. Now suppose it took you 2 seconds to lift the weight. We have said that power is work per time; therefore, the power that you have exerted is 60 foot-pounds per 2 seconds, or 30 foot-pounds per second. In engineering, a larger unit power is used: the horsepower, which is 550 foot-pounds per second.

Since power may be expressed in either watts or horsepower, you may convert from one unit to the other. One horsepower is equal to 746 watts. Therefore:

$$\frac{\text{number of watts}}{746} = \text{number of horsepower}$$

or number of horsepower x 746 = number of watts.

For further detail on electricity, refer to Basic Electricity, NavPers 10086-A. For additional information on mechanical work and power, see Basic Machines, NavPers 10624-A.

ELECTRICAL CABLE AND APPARATUS

There are many different types of electrical cables installed to suit the varying conditions of heat, cold, dryness, dampness, vibration, flexibility, and shock found on naval vessels or at shore bases.

The types of electric cable used by the Navy for shipboard wiring are identified by a standard system of lettering and numbering which gives a more detailed breakdown than do conventional stock numbers used by supply services. The letters and numbers tell exactly the kind of cable used on the run. Note the typical type and size designations in figure 7-28. The first letters tell how many conductors are in the cable.

Maximum ratings for 6SGA cables are for 400 cycle power circuits only.
*Watertight Construction

Figure 7-28.—Cables for nonflexing service.

"S" stands for single conductor, "D" for double conductor, "T" for triple conductor, "F" for four conductors, and "M" for multiple conductors to the cable.

In the 6 SGA designations, the 6 means six conductors. The other letters in the designations are the first letters of words which describe the cable further:

SGA—Shipboard General use, Armored
HFA—Heat and Flame resistant, Armored
LPA—Lighting and Power, Armored
FPA—Flame Proof, Armored.

The numbers following the letters may indicate one or more of the following:

1. Cross sectional areas of the conductor in thousands of circular mils.
2. Number of conductors.
3. Stranding of conductors.
4. Number of twisted pairs.

Two systems of cable marking (the old and the new) may be found aboard naval vessels. The old system used the color of the tag to denote cable classification and the following letters to designate power and lighting cables for the different services:

C—Interior communications
D—Degaussing
F—Ship's service lighting and general power
FB—Battle power
G—Fire control
MS—Minesweeping
P—Electric propulsion
R—Radio and radar
RL—Running, anchor, and signal lights
S—Sonar
FE—Emergency light and power

Other letters and numbers were used with these basic letters to further identify the cable and complete the designation. Typical marking of a power system for successive cables from a distribution switchboard to load would be as follows: feeder, FB-411; main, 1-FB-411; submain, 1-FB-411A; branch, 1-FB-411A1; and subbranch, 1-FB-411-A1A. The feeder number, 411, is indicative of the system voltage. The feeder numbers for a 117- or 120-volt system would range from 100 to 199; for a 220-volt system, from 200 to 299; and for a 450-volt system, from 400 to 499. The exact designation for each cable is given on the electrical wiring plans of each vessel.

The new system for marking power and lighting cable indicates the source and, where practicable, the destination of the cable. Therefore, a thorough knowledge of the system for numbering electrical machinery and equipment aboard ship is necessary to fully understand the new system of cable marking. The general rule for numbering machinery and equipment is used for numbering similar units of electrical machinery or equipment.

The general rule for numbering machinery and equipment states, in effect, that:

1. All similar units in the ship comprise a group, and each group is assigned a separate series of consecutive numbers beginning with 1.
2. Numbering begins in the lowest foremost starboard compartment, and the next compartment selected is to port of the first if it contains similar units; otherwise the next aft on the same level.
3. Proceeding from starboard to port and from forward to aft, continue the numbering procedure until all similar units on the same level have been numbered; then continue on the next upper level, and so on, until all similar units on all levels have been numbered.
4. Within each compartment, the numbering of similar units proceeds from starboard to port, forward to aft, and from a lower to a higher level.

Switchboards or switchgear groups supplied directly from ship's service generators are designated 1S, 2S, and so on as necessary to designate all ship's service switchboards. Switchboards supplied directly by emergency generators are designated 1E, 2E, and so on, as necessary to designate all emergency switchboards. Switchboards for special frequency (other than the frequency of the ship's service system) a-c generators are designated 1SF, 2SF, and so on, as necessary to designate all special frequency switchboards. Switchboards for coolant-pumping power generators are designated 1SC, 2SC, and so on, as necessary to designate all such switchboards. These designations are used only where the coolant-pumping power generators are separate from the ship's service generators.

Sections of a switchgear group other than the generator section are designated by an additional suffix letter starting with the letter, A, and proceeding in alphabetical order from left to right (it is assumed that the viewer is facing the front of the switchgear group). See switchgear group Nos. 4S and 6S (figs. 2-21 and 2-22), respectively.

Some large naval vessels are equipped with zone control, a system of ship's service distribution wherein the ship is divided into areas generally coinciding with fire zones, as dictated by the damage control plan of the ship. Power is distributed within each zone from load center switchboards located within the zone. Load center switchboards and miscellaneous switchboards for ship's service distribution systems on vessels with zone control are given identification numbers, the first digit of which indicates the zone and the second digit the number of the switchboard within that zone, determined in accordance with the general rule for numbering machinery.

The Bureau of Ships has adopted the channel method of illustrating cable diagrams. This method eliminates the use of individual lines to represent each cable and instead employs a heavy line to illustrate more than one cable, with the cables fanned out and identified at terminating points. The method reduces drafting time and also the size of drawings.

A few types of electrical apparatus are described in this section. To supplement this reading, take every opportunity to gain a first-hand acquaintance with electrical equipment and devices.

A generator transforms mechanical energy into electrical energy. It contains stationary field coils and a rotating element, also containing coils, which is called the armature. The rotation of the armature causes the conductors in the coils to cut through a magnetic field set up by the field coils, thus generating an emf. The emf causes an electric current to flow through the circuit of which the generator is a part. It may be built to generate either an a-c or a d-c current.

A battery sets up an emf by chemical action on metallic plates. Some batteries, such as common dry cells for flashlights, cannot be recharged and are thrown away when their chemical energy is spent. Storage batteries, however, with proper care, can be recharged and used many times.

In construction, an electric motor is very similar to a generator, but its use is to take power from the circuit and transform it into mechanical energy. Motors, like generators, have varied types of windings and mechanical features.

Transformers are used in a-c circuits to increase or decrease the voltage. They have a primary coil, energized by a generator, which sets up a constantly varying magnetic field and this serves to induce a current in the secondary coil. The voltage is increased or decreased in proportion to the number of turns in the primary coil to the number of turns in the secondary coil. For example, if the primary has 1,000 turns and the secondary has 100 turns, the secondary voltage will be approximately one-tenth of the primary voltage; if the primary coil has 100 turns and the secondary 1,000, the secondary voltage will be about 10 times that of the primary.

Switches are the control valves for electric current. A switch in a position of contact is said to be closed and, since the circuit is continuous, current can flow. A switch in an open position breaks the circuit and, when a circuit is not continuous, current cannot flow.

Central points in an electrical system, such as a power station or the generator room on a ship, usually have switchboards or control panels. Mounted on these are all the necessary devices for measuring and regulating the flow of current into various branches of the circuit.

A relay is a type of switch which is not operated by hand but by some force such as an electromagnet or a heating element. The purpose of a relay is to perform its switching operation at a location remote from the operator or, if a heating element is involved which trips the relay, as a protective device against too much current flowing on the line. When the relay is used as a protective device, it is usually called a circuit breaker.

ELECTRIC POWER SYSTEMS

Electric power furnishes the numerous services that are indispensable to the operation of a modern naval vessel. Because of the extensive and highly diversified use of electricity aboard ship, the electric system comprises a great many different items of equipment for the generation, distribution, and utilization of electric power.

The type of ship determines whether the electric power system is an a-c or a d-c system. The general practice is to install a-c systems in a new construction cruisers, aircraft carriers, destroyers, escort vessels, submarine chasers, and numerous auxiliary vessels.

D-c systems are used in numerous vessels converted for Navy use, and in cruisers, destoyers, and other vessels built before the general adoption of a-c ship's service systems.

The ship's service electric plant comprises the ship's service generator sets, which are driven by steam turbines, diesel engines, or gas turbines. These generator sets supply power to the ship's service power distribution system, which is the normal source of power to the ship's electrical equipment and machinery.

The emergency electric plant comprises the emergency generator sets, which are driven by diesel engines or gas turbine engines. If power is not available from the ship's service generators, the emergency generators supply a limited amount of power to the vital auxiliaries through the emergency power distribution system.

The power distribution system is the connecting link between the generators that supply electric power and the electrical equipment that utilizes this power to furnish the various services necessary to operate the ship. The power distribution system comprises the (1) ship's service power distribution system, (2) emergency power distribution system, and (3) casualty power distribution system.

Ship's Service Power Distribution System

The ship's service power distribution system is the electrical system that normally supplies electric power to the ship's equipment and machinery. The switchboards and associated generators are located in separate engineering spaces to minimize the possibility that a single hit will damage more than one switchboard.

The ship's service generator and distribution switchboards are interconnected so that any switchboard can be connected to feed power

10028

With perfect circuit elements and smooth electron emission, the circuit would oscillate indefinitely at this amplitude. But minute irregularities occur in the movement of electrons through resistors and conductors; also the emission from a cathode is not uniform. The nonuniformity is slight, but it does affect the equilibrium in the oscillator circuit. Any slight decrease in current decreases the feedback; and if the time constant of the RC circuit is not extremely long, the bias is reduced slightly by discharge of the capacitor. The decrease in bias allows a little more plate current, which reestablishes the equilibrium at the previous level.

In a circuit with a long RC, however, the circuit starts oscillating, then settles down to a balanced condition as previously described, but any slight decrease in plate current will not be compensated by lowered bias (as shown in fig. 12-24 (B)). The capacitor discharges slowly, and the continued high bias prevents feedback from being restored to the proper level. After a few cycles the oscillation dies out completely. The capacitor slowly discharges, and when its voltage drops below the cutoff voltage, the current again flows and the process repeats.

For continuous operation, the RC of the self-biasing circuit must be short enough to allow automatic adjustment of the bias for changing conditions in the circuit. To make the circuit oscillate briefly, then stop, a long RC is used. The time the tube remains cut off depends upon both the grid capacitance and grid resistance. By proper selection of these values, the oscillator may be made to operate for 1 or 2 microseconds and then cease operation for 500 to 1,000 microseconds.

Grid voltage variations are shown in figure 12-25. It is not possible to show the actual time relations, since the OFF period is several hundred times as long as the ON period.

In an equipment using a self-pulsing oscillator it may be necessary to synchronize the oscillator with other circuits. This may be done by applying a synchronizing sine wave to the grid. The results are shown in figure 12-25 (B) and (C). Without synchronization (A), the grid rises exponentially and crosses the cutoff line at a small angle, which means that the actual time at which oscillation begins may vary somewhat. Notice in (C) that the point at which the grid voltage crosses the cutoff bias line is much more definite.

Figure 12-25.—Grid waveshape with and without sync.

The ideal condition would be for the grid voltage to cross the cutoff line at a 90° angle. For that reason, a positive going pulse is often applied when the grid voltage approaches cutoff. This assures oscillation at exact intervals of time. The oscillator is then synchronized to produce a desirable PRF.

Another means of obtaining a sharp crossover angle of the grid voltage is to return the grid to a positive voltage rather than to ground. Thus the grid voltage, in rising to a higher voltage than zero, will cross the cutoff line at a steep angle.

In order to make the DURATION of the pulse more definite, some self-pulsed oscillators use an artificial transmission line (pulse line) instead of the grid leak capacitor. This has the added advantage of making the operating conditions more nearly constant throughout the pulse. There are two places where the pulse line can be located. One is to put it in the grid circuit, as shown in figure 12-26, the other, in the cathode circuit.

A pulse line behaves like a long transmission line. It acts like a resistive circuit until the charging pulse has traveled the length of it and returned, at which time it is fully charged. This causes the voltage to change in two steps; the first step is from the bias level to the voltage determined by the product of the grid current times the characteristic impedance of the line, and the second step is of a magnitude equal to the first.

1000

from its generators to one or more of the other switchboards.

Emergency Power Distribution System

The emergency power distribution system is provided to supply an immediate and automatic source of electric power to a limited number of selected vital loads in the event of failure of the ship's service power distribution system. The system, which is separate and distinct from the ship's service power distribution system, includes one or more emergency distribution switchboards. Each emergency switchboard is supplied by its associated emergency generator. The emergency feeders run from the emergency switchboards and terminate in manual or automatic bus transfer equipment at the distribution panels or loads for which emergency power is provided.

The emergency generators and switchboards are located in separate spaces from those containing the ship's service generators and distribution switchboards.

Casualty Power Distribution System

The casualty power distribution system is provided for making temporary connections to supply electric power to certain vital auxiliaries if the permanently installed ship's service and emergency distribution systems are damaged.

The casualty power system includes portable cables, bulkhead terminals, risers, switchboard terminals, and portable switches. Portable cables in suitable lengths are stowed throughout the ship in convenient locations.

I.C. SYSTEMS

Alarm and Warning Systems

Alarm and warning systems are provided in naval vessels to indicate abnormal or dangerous conditions that may cause casualties to machinery and personnel.

The various alarm and warning systems used aboard ship are usually the simplest types of I.C. circuits. The majority of these systems consists of one or more switches that complete an electric circuit to various types of audible and visible alarm equipment. There are many kinds of switches in use and the type depends upon the circuit in which it is installed. Relays are used in alarm and warning systems to open and close circuits that may operate indicating lights, annunciator drops, and/or audible signals. Audible signal devices include bells, horns, buzzers for quiet spaces, and sirens for noisy spaces or to sound very urgent alarms.

Visual signals are used in a great many alarm and warning systems to provide an additional means of identifying the alarm being sounded. Audible and visual signals are often used together. In many instruments the same audible device is used in combination with several visual indicators. The principal types of visual signals are lamp-type indicators and annunciators.

Announcing and Intercommunicating Systems

Shipboard announcing and intercommunicating systems serve the general purpose of transmitting orders and information between stations within the ship by amplified voice communication. This function is accomplished by either (1) a central amplifier system, or (2) an intercommunicating system.

Each announcing and intercommunicating system installed aboard ship is assigned an I.C. circuit designation in the MC series. Authorized I.C. announcing circuits are numbered 1MC through 34MC. These systems, however, are not all installed in any one ship.

The central amplifier announcing system is designed to furnish amplified voice communications and alarm signals to the various loud speaker groups aboard ship. The system provides for transmitting the spoken word or signal at any one of several stations, amplifying this signal from a number of loudspeakers.

An intercommunicating system consists of a number of identical, permanently located stations. Each station contains all the necessary components to provide two-way amplified voice communication, supplemented by signal lamps, between any two stations or from one station up to four other stations simultaneously.

Supplementary Communication Systems

The sound-powered telephone amplifier system provides a method of amplifying one-way communication (incoming speech) in a two-way sound-powered telephone communication system. The equipment is designed to amplify voice signals so that the reproduced message will be clear and understandable at locations aboard ship where the noise level is high (gun positions

or machinery spaces). When the amplifier is turned off, the system functions normally for two-way communication at the sound-powered level.

The dial telephone system is primarily an administrative circuit that provides complete selective telephone communication throughout the ship. This system is also used to supplement other communication facilities for ship control, fire control, and damage control. The capacity of the system varies with the size and needs of the particular ship.

Television is becoming increasingly important in Navy applications. Present applications are limited to closed circuit television. In the closed circuit systems, signals are sent between the camera and the receiver through cables instead of through the air.

Ship Control Order and Indicating Systems

Ship control order and indicating systems include among others the engine order system, propeller order system, rudder order system, and rudder angle indicator system. These systems comprise units that pertain to ship control orders and indications.

Ship's Metering and Indicating Systems

Ship's metering and indicating systems include the shaft propeller revolution indicator systems, wind direction and speed indicator system, salinity indicator system, underwater log system, and many others.

DRAWINGS AND SYMBOLS

Electrical diagrams may seem less difficult to draw than complex projections of machine parts or structural drawings. The standard symbols used on electrical diagrams consist of simple shapes: lines, circles, squares, rectangles, and letters. But try to read an electrical diagram with no key to the symbols and you will begin to appreciate the difficulty involved in making such a drawing.

A draftsman usually follows the accepted standards and methods of the organization or activity to which he is attached. These are governed by considerations concerning the purpose of a drawing and who will use it.

There are a number of ways of classifying the different types of electrical drawings. Actually they may range from a scale drawing of some electrical apparatus, which shows exact location of all wiring and connections, to a schematic diagram, which is not drawn to scale and which shows none of the actual construction details of the system. In figure 7-29, a pictorial drawing, and elementary wiring diagram, and a schematic are compared. They show exactly the same thing—an ignition system—but they look quite different.

Actually the schematic diagram is usually the first drawing worked out by the designer. It denotes the scheme of things. It corresponds to the design drawing of mechanical drafting, except that it is not drawn to scale and does not look in any way like the finished wiring will look. From it, a wiring diagram or an electrical layout with accompanying scale details may be drawn.

Shipboard wiring diagrams may be classified under four general headings: elementary wiring diagrams, schematic wiring diagrams, isometric wiring diagrams, and wiring deck plans. The elementary wiring diagram, as the name implies, shows each individual conductor in the circuit and every connection made. Most of these diagrams do not show the fixtures or cable runs, and for this reason they are not drawn to scale. What they show are the structural parts of the circuit. An elementary diagram would be used to check proper connections in a circuit or to make the initial hook-up.

Schematic wiring diagrams, on the other hand, would show the order in which parts of the system are connected but would not show each individual conductor. An example of a schematic diagram of a power distribution system in a destroyer is shown in figure 7-30.

As explained earlier, MIL-STD-7A defines the various types of engineering drawings and gives examples which follow the standard format. Figure 7-31 shows a sample single line diagram drawing from MIL-STD-7A.

The symbols to be used on ships' plans are set forth in Electrical Wiring Equipment Symbols for Ship's Plans, MIL-STD-15-2. Typical standard symbols are shown in figure 7-32. Buildup, or composite, symbols can be contrived from basic symbols. Letter combinations used as parts of the graphical symbols do not constitute abbreviations as the term is used in the standards. For abbreviations as such, refer to MIL-STD-12.

MIL-STD-15-2 does not cover all of the symbols to be used for diagrams of the circuitry inside items of shipboard electronic equipment—these symbols will be found in MIL-STD-15-1. MIL-STD-15-2 does cover, however, the symbols for the wiring appliances used in the power supply systems of electronic equipment.

The block diagram is the simplest type of electrical drawing. Figure 7-33 shows a typical block diagram.

The typical schematic wiring diagram, such as the one shown in figure 7-34, is more detailed.

The schematic diagram in figure 7-35 shows how various drawing techniques can be combined on one drawing. The upper part is a conventional schematic diagram. The lower part, however, is an oblique drawing of the cables which follow the outline of the hull of the ship.

0037

Figure 12-26.—Oscillator, with plause line in grid circuit.

The PRF is controlled by the synchronizing pulses, but the discharge of the pulse line through the grid resistor must be such that the grid voltage approaches the cutoff point by the time the next synchronizing pulse comes in. The discharge of the line is in steps, as shown in figure 12-27, which is the diagram of the grid waveshape of a line controlled, self-pulsed oscillator. The magnitude of the discharge voltage is determined by the relative values of the grid resistance (R_g) and the characteristic impedance of the line. R_g is usually much larger, hence the steps are small. These steps follow the general path of the exponential discharge curve with time constant R_gC_o, where C_o is the capacitance of the pulse line.

Figure 12-27.—Grid waveshape of a line controlled, self-pulsed oscillator.

Separate Modulators

As previously mentioned, some triode UHF oscillators are not self-pulsed, but employ separate modulators. These modulators are very much like those used with magnetron oscillators, which are discussed later in this chapter. Here merely note that the oscillator may be plate modulated, grid modulated, or cathode modulated.

PLATE MODULATION.—Figure 12-28 (A) shows a circuit for plate modulation in which short positive rectangular pulses applied to the grid of the modulator tube result in a negative going pulse at the plate.

Plate voltage is applied to the oscillator tube or tubes in short rectangular pulses. RF components for the oscillator are not shown in the diagram. The transformer must be specially constructed so that it passes the rectangular pulse without undue distortion. Since one purpose of the transformer is polarity inversion, the question arises as to why negative going pulses are not applied to the grid of the modulator tube to cut it off and obtain a positive going pulse at the plate for use in modulating the oscillator. This would require that the modulator tube, or tubes, conduct heavily during all the cycle except during the pulse, and would result in excessive waste of power.

The grid capacitance C_g of the oscillator is quite small, usually consisting of only the capacitance to ground of the grid tuned circuit. If made too large, C_g might cause the oscillator to be self-pulsed and cut itself off before the modulator pulse is over. C_g and R_g have values that would cause continuous wave operation if plate voltage were applied all the time. The modulator pulse is most effective in controlling the output pulse. Oscillations must build up rapidly so that the leading edge of the output pulse will be as steep as possible. The plate voltage of the oscillator must remain constant throughout the pulse.

CATHODE MODULATION.—A cathode pulsed (modulated) oscillator does away with the necessity of inverting the pulse, hence no transformer is required. (Refer to fig. 12-28 (B).) The charging diode serves to recharge the coupling capacitor C between pulses. The capacitor must have a large capacitance, so that it will not discharge appreciably during the pulse and thereby lower the plate to cathode voltage.

0001 1001

CHAPTER 8

OFFICE MACHINES AND EQUIPMENT

In most every graphic art shop there is an assortment of machines and equipment used daily in the production or reproduction of illustrative material. It may also be a command instruction that a DM be the projector operator when the command gives its presentations. This chapter covers only a few of the many different types of equipment available; and, because of the almost constant changes and improvements in office reproduction equipment, the equipment in your office may be far in advance of that covered here, or it may be quite obsolete compared to the equipment mentioned here. The one thing any operator of any piece of equipment should always do is to study the manufacturer's instruction book which comes with his particular machine. This is the most practical method of learning the operation, maintenance, and safety precautions pertaining to any specific machine.

PROJECTORS

OVERHEAD PROJECTOR

The overhead projector is used to project images from either transparencies or slides. Light from a 500 or 1000 watt projection lamp is reflected upward toward the projection stage. Supported centrally over the stage is the projection level. Light leaving the lens along a vertical axis is deflected toward the screen. Figure 8-1 depicts the nomenclature of the overhead projector and shows the path of light being projected.

The projector can be set up on either side of the screen. For classroom use, it is more effective for it to be located in front of the screen to allow the instructor to operate it while he is instructing his class. The instructor can face his class continuously and can time his demonstrations during the class period to maintain greater trainee attention.

For command briefings, the projector is usually placed behind the screen so that it offers no interference to the audience.

There are projectors which project transparencies of 5 x 5 inches, 7 x 7 inches and even 12 x 15 inches, but the projector most commonly used has a 10 x 10 inch aperture.

In addition to projection capability, mechanical simplicity is a great advantage. It has the lamp (easily replaced) and a small blower for cooling, but no gears, wheels or dials. Turn on the lamp and it's ready for projection.

Lantern Slide Attachment

The attachment (fig. 8-2) is designed for the projection of standard lantern slides (3 1/4 x 4 in.). It consists of a collar, slide platform, auxiliary lens assembly and auxiliary lens. To mount the slide platform, remove the tube from the projector and slide the platform onto the tube from the bottom up until it approximately touches the rack. Tighten the clamping screw slightly. Slide the collar onto the tube so that the raised side of the collar comes in contact with the platform to serve as a stop. Tighten the clamping screw. Reinsert the tube into the projector and clamp it. Swing the platform until it is approximately centered over the projection stage. Mount the auxiliary lens as shown in figure 8-2. Push the clamping ring over the bottom of the lens so that the bottom edge of the lens and ring are even. Carefully tighten the clamping screw.

Turn on the projection lamp. Swing the platform from side to side until the bottom edge of the screen image is parallel to the floor. Rotate the collar until the vertical projecting edge

10038

Figure 8-1.

comes up against the platform casting. Clamp the collar in this position. This serves as a stop so that the platform can be swung in and out of the projection position instantly. The auxiliary lens is also pivoted so that it can be swung in and out of operation position instantly.

To project slides, place the auxiliary lens and platform into projection position. Focus the image with the focusing knob. While one slide is being projected the next slide can be placed in the channel beside the first one. The slides are changed by sliding the second slide into projection position. This enables uninterrupted projection without light flashes on the screen.

Lantern Slide and 2" x 2" Slide Attachment

The lantern slide attachment (fig. 8-3) is designed for the projection of lantern slides (3 1/4" x 4") and 2" x 2" slides. It consists of a collar, a platform, a platform for 2" x 2" slides and an auxiliary lens assembly consisting of a clamping ring, lantern slide auxiliary lens, and 2" x 2" slide auxiliary lens.

Note: The lantern slide attachment in figure 8-2 can be converted into the lantern slide and 2" x 2" attachment by the addition of the 2" x 2" auxiliary lens and the 2" x 2" slide platform.

To mount the attachment, follow the instructions given for the lantern slide attachment shown in figure 8-2. Mount the 2" x 2" slide platform by hooking it over the shoulder rivets on the lantern slide platform. Figure 8-3 shows the unit set up for the projection of 2" x 2" slides. To project standard slides, remove the 2" x 2" platform and swing the 2" x 2" auxiliary lens to one side.

A HEAT ABSORBING FILTER is required for the projection of 2" x 2" slides and 35mm film strips. It is furnished mounted on a plate and is inserted into the projector by simply sliding it into the channels. (See fig. 8-4.) Although the heat absorber must be used, even with the 500-watt lamp, when projecting 35mm film strips and 2" x 2" slides, it is not normally required

Figure 8-2.

Figure 8-3.

Figure 8-4.

Figure 8-5.

for other types of projection, even with a 1000-watt lamp, unless the transparency being projected is very dense. In this case, most of the energy in the beam of light is arrested and converted into heat, making the heat absorber necessary.

35mm Film Strip Attachment

Projection of 35mm single and double frame film strips is accomplished by means of the film strip attachment used in conjunction with the Standard Slide and 2" x 2" Attachment.

This attachment is mounted in place of the 2" x 2" slide platform. It is placed with the feeding knob (fig. 8-5) toward the screen.

Single frame film strips are projected in the vertical position as shown. Double frame film strips may be projected in either the horizontal or vertical position by means of a turret which permits turning the upper portion of the attachment perpendicular to the position shown.

The attachment includes two identical pressure plates and a single frame mask. These are located above the retaining knob. The mask must be removed when projecting double frame film strips. Both the aperture plates and the mask can be removed by depressing the retaining knob.

To thread the film, hold it with the emulsion (dull) side up and insert the front end between the two pressure plates just above the retaining knob. Push the film through and at the same time turn the feeding knob counterclockwise. The film will automatically engage itself.

OPAQUE OBJECT PROJECTOR

The basic difference between the opaque object projector and the overhead or film or slide type is that light is reflected from the surface of the opaque object (see fig. 8-6) instead of passing through the slide or transparency. Examples of opaque objects that can be projected with this device are a page of a magazine or book, photographs, pictures in full color, charts and diagrams. Also, relatively flat physical objects such as small machine parts, cams, gears, coins, etc., can be projected. No special preparation of the opaque objects is necessary in order to project them.

The opaque object projector can be used as a visual aid in teaching and briefing, for the presentation of progress charts and similar data and for the comparison of small physical objects. It is extremely useful to enlarge drawings, maps or photographs so that they can be traced proportionally correct and in complete detail.

The projector uses a 1000-watt projection lamp, has a projection opening of 10" x 10", and is equipped with a 4 1/2" diameter, 22" focal length lens. The projector is equipped with an opaque object holding device and a conveyor belt type loading mechanism which permits uninterrupted projection. The projector is provided with an optical pointer by means of which details anywhere on the screen can be pointed out by a projected light spot.

The roll feed assembly provides a means for handling opaque objects of any length and up to 10" wide. The thickness of the objects should not exceed 1/32". The feed assembly

Figure 8-6.

also permits inserting and removing the copy without lowering the platen (see fig. 8-7) assembly. The maximum size of the opaque object that can be projected at one time is 10" x 10".

To operate the roll feed assembly, stand behind the projector and hold the crank in your right hand. Hold the copy in the left hand, face up, bottom edge toward the screen and feed it into the left side of the projector. When the material is inserted approximately 1 1/2", turn the crank clockwise. The pressure created by the impelled air will hold the opaque object flat on the feed belt and when the crank is turned, the opaque object is carried into position. When the next opaque object is inserted, repeat the operation. Insertion of one opaque object automatically removes the previous one. To project thick objects (up to 1 1/2" thick), lower the platen assembly to the locked position and remove the roll feed assembly by lifting it off.

10041

Figure 8-7.

Place the opaque object upon the platen assembly and let it rise as far as it will go. Apply a continuous pressure downward on the platen handle to prevent the platen assembly from snapping upward when you release the lock.

Although thick physical objects (not lying in one plane) can be projected, only one plane of the object can be brought into focus at one time. Other planes can be brought into focus by rotation of the focusing knob. However, when an object is not too thick, good definition can be obtained over its entire thickness.

Set the projector on a suitable table in the projection room. The table should be high enough to project the image over the heads of the audience. Do not use a low table which requires excessive extension of the elevating legs as this will produce a distorted screen image which will be impossible to focus sharply. With the opaque projector, the screen illumination obtained is not great and it is necessary to use a dark room for satisfactory projection.

LANTERN-SLIDE PROJECTOR

The lantern-slide projector is specifically designed for auditorium and theater projection of standard 3 1/4" x 4" lantern slides, 2 3/4" x 2 3/4" slides, and 2" x 2" slides. Some models of this type of projector have built-in optical pointers. The projector uses a 750-watt lamp, is blower cooled and has an extremely wide range of objective lenses available. Figure 8-8 shows the standard lantern-slide projector.

35MM STRIP FILM AND 2" x 2" SLIDE PROJECTOR

The film strip is projected through the projector, frame after frame, by turning the film advance knob (fig. 8-9) counterclockwise. The strip film attachment assembly is designed to automatically transport and index into position each single or double frame. The framing mech-

Figure 8-8.

10042

Figure 8-9.

anism is arranged so that 1/4 turn (1/4 of a full revolution) of the film advance knob transports and indexes one complete single frame, and 1/2 turn (1/2 of a full revolution) of the film advance knob transports and indexes one complete double frame. In either case, the film advance knob tends to carry through the necessary movement to index the strip film in the proper frame position. It is best for the operator to turn the film advance know several times before the presentation begins in order to get the feel of the knob.

To reverse the direction or to repeat a picture, turn the film advance knob clockwise.

To project slides placed in the slide carrier assembly (fig. 8-10), use the slide carrier knob to push or pull the slide carrier from one side to another. The slides, in either compartment, are automatically indexed in position for proper projection. While the first slide is being projected, place the second slide into the exposed compartment of the slide carrier. Push or pull the slide carrier to the other side to project the second slide. While the second slide is being projected, remove the first slide ~~and insert the~~ third into the same compartment, then push or pull the third slide into projection. Continue this procedure until all slides have been projected.

DIAZO

DRY PRINT PROCESS

The diazo dry print process allows for fast, continuous reproduction on either paper or clean foils which are then used in conjunction with the overhead projector. There are diazo machines of various sizes but all of them work on the same principle. The original or translucent material is placed on a sheet of sensitized paper or foil (with sensitized side face up) and both are fed into the machine. Belts convey the two sheets around a high pressure mercury lamp (printing cylinder). Here the material is exposed to ultra-violet rays from the pressure mercury vapor lamp. The ultra-violet light source quickly inactivates all the dye on the sensitized paper that is not covered and protected by the opaque image of the original. The printing speed depends on the translucency of the original and the density of the lines, and on the type of sensitized materials used. With some machines, after the exposure is made, the ma-

Figure 8-10.

APOO110043

Figure 8-11.

terials are picked off the cylinder and guided to separation devices. At this point the print and original are automatically spearated and the print is conveyed to the developer section. The original is returned to the tracing receiving tray by a rubber disk ejection roller.

After exposure, the sensitized sheet contains only the exact image of the original. It is now conveyed across ammonia vapor, which develops the image and makes it as permanent as the paper itself.

The ammonia solution is heated to generate ammonia vapors that serve as the developing agent.

The print may have blue, black, red, or sepia lines. It may be on several grades or weights of white paper or on blue, pink, yellow, or green paper, or on film, cloth, or plastic-coated paper. Completely dry, it is ready for immediate use. Chapter 19 contains more information on the assortment of papers, foils and material available and how to use them. Figure 8-11 shows a diagram of the diazo process.

OTHER EQUIPMENT

It will be seldom that any of the graphic art shops in the assorted commands will have the same office machines and equipment. The machines just covered will be found in nearly all graphic art shops and some commands will have more, while some will have less. Some of the machines are the THERMOFAX, VERIFAX, ZEROX, PHOTOCOPIER, and several more. Some of these machines are very new in development and are constantly being improved and modified. As has been stated and now reemphasized, the only way anyone can truly learn the equipment he is to be associated with is to study the instruction books for the particular machines which are usually prepared by the manufacturer and contain information on how to operate and maintain the machines. They also explain safety procedures and replacement of parts. You should never operate any machine before you become thoroughly familiar with it. This is for your safety and for the safety and protection of the machine.

C4000010044

CHAPTER 9

LETTERING

Lettering has often been called AN ART IN ITSELF. As an art, handlettering requires many hours of study and practice. It is extremely important for you to perfect your hand lettering if you are to become a qualified Illustrator Draftsman. You must know what makes one alphabet easier to read than another, what gives one alphabet more beauty and character than another, and you must be able to visualize appropriate letter forms in your mind.

An understanding of the letters and the ability to visualize them can be accomplished by the practice of drawing them until the muscles of your hand are accustomed to the pattern of the strokes which makes up the letters. You should be able to draw good letters without consciously thinking of this pattern. So, in order to letter well and use lettering effectively in your work, good taste in selecting the proper alphabet for the job, an ability to visualize, and highly trained hand muscles are needed.

As an Illustrator Draftsman, you will be required to do lettering for official publications, posters, placards, and do display lettering as well as doing the lettering on technical drawings.

The illustrative lettering can be accomplished freely, limited only by the dictates of good taste and suitability of the particular lettering style. Within these limitations, you are free to use originality and imagination; whereas, on the technical drawings, you are required to follow definite lettering specifications.

When you are lettering, regardless of type or purpose, the one rule you must always follow is to make your letters legible. Letters that are legible make it easier for the reader to understand the message before him.

When lettering, you may take your choice of a number of different materials, and it is your business to know which materials to use when you wish to draw a particular kind of letter. The materials necessary to do layout lettering are paper and pencils.

The most useful paper used in layout lettering is the visualizing paper. It is transparent enough to see through to the tracing beneath. Layout lettering is usually done directly on the visualizing paper pad.

The type of pencil used is a matter of personal choice; however, you should have at least a soft and a medium grade sketching pencil. A carpenter's pencil with its broad flat lead is a favorite of many illustrators when they are lettering. Layout pencils are used for medium size letters and regular drawing pencils of various degrees of hardness are used for smaller letters.

The layout should be true and accurate in size and shape. If available, a good steeledged T-square and a triangle should be used to keep the layout as square as possible.

A printer's ruler is used to indicate size when the drawings are to be reproduced. The printer's ruler is graduated in picas and half picas, having 6 picas to the inch. More precise rulers have the pica graduated in points, having 12 points to a pica. A printer's rule is shown in figure 9-1.

A pair of dividers used for spacing the letters and erasers such as artgum, ruby, and especially kneaded erasers are a must when doing layout lettering. When a lettering job is completed, it is cleaned, then sprayed with a fixative to keep it from smudging.

In the graphic arts and printing practices, a short word for alphabet is FACE, and we will use it from now on.

Everyday we can see seemingly countless styles of lettering in every direction we turn. In reality, all of these many styles have a great deal in common. Almost all faces are variations

10045

Figure 9-1.—Printer's rule.

of one simple face which is called the BASIC FACE. This face is composed of 26 capital letters, 26 small letters and the numbers 0 to 9. The term CAPS is used professionally for the capital letters and the term LOWER CASE is used to specify the small letters.

All letters are made of one or more parts called STROKES. In the roman face, some strokes are thick and some strokes are thin. With the gothic face, all strokes are of about the same thickness.

THE BASIC FACE

All of our many roman and gothic faces are represented by the basic framework of the basic face. The letters in figure 9-2 have been stripped down to their essential elements. None of the letters can be constructed in a more simplified style than that which is shown. Each of these letters, caps, lowercase, and numbers, should be studied until its construction is known by heart.

The first step in drawing the basic face in figure 9-2 is to establish the height of the letters to be drawn, then draw light parallel guidelines with your pencil. Normally, the main body of the lowercase letters is about two-thirds the height of the caps.

Figure 9-2.—Basic lettering.

THE ROMAN FACE

Our capital letters come to us from the ancient Romans who developed and perfected them. The ancient artists carved their letters in stone, and as a guide, they first painted the letters on with a flat brush, which was always held at the same angle. When the brush was

Figure 9-3.—Portion of an inscription on base of Trajan Column, Rome, circa 114 A.D.

10046

moved sideways, it made a thin stroke, and when moved up or down, made a thick stroke. The artist then cut away the painted stone with a chisel. Figure 9-3 shows an example of the ancient Roman's lettering.

Figure 9-4 illustrates this thick and thin principle which the Romans used, and shows four of the most commonly used flat lettering tools.

A square chisel point on a carpenter's pencil is the ideal tool to use when drawing the roman face. You can LET THE TOOL FORM THE LETTER. Figure 9-5 shows how the chisel point is formed and shows the recommended position for using it. Your thick and thin strokes will come automatically if you train yourself to hold the pencil so that the chisel point forms about a 30° angle with the horizontal guidelines.

Figure 9-4.—Four common lettering tools.

Do not twist or turn your hand as the strokes turn, but hold your pencil at the same angle at all times. You will find it necessary to re-sharpen your pencil often in order for your strokes to all have the same sharp edges.

To work well, sit comfortably with your work directly in front of you. Don't lean over too close to your work. You want to be able to see all of your work in order to relate each letter to the entire layout. Except when touching up, always keep your pad straight on the drawing board.

THE THICK AND THIN ROMAN FACE

At this point you should have pretty well mastered drawing the Basic Face, so now we are ready to learn the basic strokes of the thick and thin roman face.

To draw the thick and thin roman face in figure 9-6, you draw the same basic face as in figure 9-3 except you use a chisel-pointed pencil. In figure 9-6, number arrows indicate the sequence and direction in which each stroke is to be made.

A general rule to follow when lettering is to draw two guidelines indicating the height of the caps. If you are combining lower case with the caps, a third line is added so that the lowercase letters are about two-thirds as high as the caps. The height of the lowercase letters will vary with the different faces, but for general purposes, the use of the 2/3 to 1 scale is a good practice.

Figure 9-5.—Chisel point lettering.

Figure 12-28.—Pulse modulation systems.

GRID MODULATION.—Grid modulation requires less power from the modulator for operation than either of the other two types of modulation. A positive going rectangular pulse is applied to the grid and raises the grid voltage well above the cutoff points so that oscillation starts. Oscillation ends whenever the grid voltage drops to the normal bias. Usually the arrangement for this purpose is the one in which oscillation is started by a positive trigger pulse and ended by a self-pulsing grid bias voltage. C_g in the grid-pulsed oscillator shown in figure 12-28 (C) is a small capacitance and is used to couple the pulse from the cathode of the modulator tube to the grid of the oscillator to insure a rapid rise of voltage at the grid and cause oscillations to build up quickly.

MODULATING THE MAGNETRON OSCILLATOR

The modulation circuit for the magnetron serves a double purpose—it determines the waveform of the output pulse, and it stores energy between pulses and releases it through the magnetron during the pulse. A typical circuit of a modulator and magnetron is shown in figure 12-29. This discussion will explain the theory of operation of the line pulsing modulator, and will also explain and/or summarize the functions of the various components.

The pulse forming network undergoes a charge-discharge cycle at a rate (PRF) which is established by the master trigger generator, and which is consistent with the pulse width in use and with the maximum power capabilities of the transmitter. The modulator consists of an artificial line pulse forming network (Z1), thyratron switch tube (V1), holdoff or charging diode (V2), inverse diode (V3), resonant charging choke (L1), and magnetron pulse transformer (T2). The double wound secondary of transformer T2 supplies a pulse of power to the magnetron cathode circuit each time the pulse forming network (PFN) is discharged. The switching device which controls the discharge of the line is the thyratron, controlled by the trigger pulse from the radar synchronizer.

When system power is applied, current to charge the PFN is drawn from the power supply through L1 and V2. This current flow establishes a magnetic field in the choke. Charging is rapid until the charge on the PFN is nearly equal to the peak power supply voltage.

1002

Figure 9-6.—Basic Roman face.

The ascender is the part of the lowercase letter that extends above the body of the letter. Except for the letter t, all extenders are as high as the caps. The descender is the part of the lowercase letter that extends below the body of the letter, about the same distance as the ascender raises above the letter.

Figure 9-7 illustrates the six basic strokes of the roman face. Practice these individually and in combination with each other.

CASLON FACE

With the addition of serifs, which are small strokes at the end of the main strokes, you can make thick and thin letters into the Caslon style roman shown in figure 9-8. Caslon has been selected for instruction not only because it is the most widely used, but also because it conforms most closely to the thick-and-thin style just discussed.

The Caslon face is also the most commonly used with other roman faces because its serifs are not extreme, but are average in thickness, pointedness, and length.

The Caslon letters are drawn with the same sequence of strokes as the chisel point thick and thin roman letters in figure 9-6.

Figure 9-8 shows finished Caslon letters and, beside them, the chisel point interpretation. Do not attempt to copy the finished letters in detail, but try only to show the character of the letter with the minimum of work, which is what a layout calls for.

There is one exception to the rule of holding the chisel point at the 30° angle. When you are

Figure 9-7.—Six basic strokes of the Roman face.

AABBCCDD etc

aabbcc-1122etc

Figure 9-8.—Caslon face.

drawing the thin diagonals or verticals, as with the letters A, M, N, V, and W, the unwanted thickness in the stroke must be avoided, so the chisel point is turned so that a very thin line is made. The chisel point is not turned from the 30° angle for any other reason if good Caslon lettering is to be accomplished.

SPACING

Drawing each letter correctly is not the end of good lettering. You must be able to put the correct amount of space between each letter, between each word and between each line.

The well lettered line will look as though the same amount of space appears between each of the letters, avoiding holes caused by too much space between letters and dark areas caused by a lack of space between letters. When correctly spaced, a line will have an overall uniform pattern.

Your only real guide in proper spacing is your eye, and, because letters are not uniform in shape, your artictic talents must guide you in your spacing.

Figure 9-9 illustrates mechanical spacing and the proper optical spacing.

COMMON PROBLEMS WITH SPACING

Certain combinations of letters often create spacing problems. Figure 9-10 illustrates some of these problems and ways to overcome them.

Figure 9-9.—Mechanical and optical spacing.

Sometimes you can alter the shape of the letters, but you should never alter them so much as to make it obvious to the viewer. Never sacrifice the desired shape of the letter to obtain better spacing if the result will be poor lettering.

Of all the problems with spacing, there are six which usually present the most problem. Of these six, five can be solved by moving the letters closer together; they are:

ROUND TO ROUND

The air space (space between letters) increases at the top and bottom as the letters curve away from each other, Figure 9-10A.

ROUND NEXT TO SLANT

The same as round to round; the air space is increased by the slant of one letter and the slope of the round letter, Figure 9-10B.

VERTICAL NEXT TO SLANT

The slant of the letter increases the air space, when the letters are moved closer together; it is sometimes impossible to keep their serifs from joining, Figure 9-10C.

SLANT NEXT TO SLANT

When the slants are parallel to each other, the space is about the same as for two verticals. When they slant toward each other, they will or will nearly touch, Figure 9-10D.

ROUND NEXT TO VERTICAL

The air space increases as it did in round to round, Figure 9-10E.

049

Figure 9-10.—Common spacing problems.

VERTICAL NEXT TO VERTICAL

The last remaining problem is solved by adding more air space when possible. This is when, there is no white area cutting in to make the space look wider, Figure 9-10F.

WORD SPACING AND LINE SPACING

When a person reads a line of type, he can tell where one word ends and the next one begins because of the space left between them. When there is not enough space, the words run together; when there is too much space, they appear unrelated and difficult to read.

In addition to the spacing between letters and words, the spacing between lines of lettering adds to the readability of the lettering. Again your eye and your artistic ability must be your guide. Except when you are trying for a special effect, you should have enough air space between the lines to make it easy for the reader to see what he is reading.

LAYOUT LETTERING

The most important part of layout lettering is to obtain as nearly as possible a perfect final tracing. The number of preliminary tracings you will need to accomplish this will vary according to your ability. Sometimes you may need only one preliminary tracing, or you may need four or five or more. Regardless of how many you find you will need to do, you must work until you have the best tracing possible. The tracing is very important in determining the artistic quality of your finished layout.

You may use a T-square on the vertical and horizontal lines to get good crisp, straight lines. This is especially good on the finished layout. By using the T-square, you can give your lettering the neat, craftsman-like appearance of roman lettering. You work with your T-square on the

Figure 9-11.—Layout lettering.

Cadet Library 10021

working edge of your drawing board only and turn the drawing paper to draw the vertical lines. Never use your T-square on any edge other than your working edge.

With your well sharpened chisel pointed pencil, you can draw every stroke needed, but never hesitate to make adjustments with a pointed pencil. Figure 9-11 illustrates the steps in doing layout lettering.

Rule guidelines using a T-square and a sharp HB pencil. Rough in the letters lightly, with no attempt at refinement at this stage. The object now is to fit the letters properly to the line. With the chisel pointed pencil, letter over the light guidelines and try to have the lettering come out even in the space allowed for it.

Remove the rough sheet and insert it under a clean sheet of paper. Now try to improve your proportions and shapes; repeat the process again. If it appears you are going to run over, do not tighten up the spacing or the width of the letters; this is to be done in the next tracing.

Repeat step 2 by inserting the second tracing under another clean sheet of paper. You should be able to easily draw and space the letters to fill the line exactly this time.

Remove the third tracing and place it under the top sheet of your layout pad. Draw your guidelines lightly and, using your T-square, draw all vertical strokes with the chisel pointed pencil.

Draw the horizontal strokes using the T-square. Either freehand or using a triangle, draw in the diagonal strokes.

Draw in the curves freehand. Keep the chisel point at a 30° angle to the horizontal line. Strive for accuracy and any slight imperfection in the curves will not be very noticeable.

The last step is to stroke in the serifs. To give the lettering a crisp and even finish, use the T-square as a guide for all horizontal serifs. Add the vertical and diagonal serifs in freehand.

LETTERS OF DIFFERENT WEIGHTS AND PROPORTIONS

Letters vary in weight as well as in size.

LIGHT letters are made with thin strokes.

BOLD letters are made with wide strokes.

MEDIUM letters are in between the two above.

The weight of the letters is varied according to the width of your chisel point.

Letters that are narrow for their height are CONDENSED letters.

Letters that are wide for their height are EXTENDED letters.

When the working area is wide and there is little to say, the use of EXTENDED letters is useful, especially if a few of the words are to be given prominent display.

When a lot is to be said in a limited space, the use of CONDENSED letters is useful.

When you are practicing lettering, practice drawing letters of different sizes, using harder pencils as the sizes get smaller.

ITALIC LETTERS

The term ITALIC refers to letters that slant to the right. The degree of slant is from 10 to 30 degrees. Italic letters are widely used to show emphasis, or for a change of pace.

Figure 9-12.—Italic lettering.

10051

Figure 9-13.—Gothic face.

There is an italic version for almost every type face. The same sequence and manner used to make the roman caps are used to make the italic caps. The italic lowercase letters differ greatly from the roman lowercase letters. Instead of the serifs having curved hairlines, the ascenders of the italic lowercase have horizontal serifs, as shown on the letters b, d, h, k, and l in figure 9-12. Note how smoothly the thin lines and the hairline serifs flow into the main stems of the letters a, b, d, and q, giving the body of the letter an oval-like shape on its inside.

When you draw your horizontal guidelines, draw in your parallel diagonal lines as a guide to follow. Not all of the letters will be slanted exactly to these diagonal guidelines, but all of the letters should appear to have a uniform slant.

GOTHIC LETTERS

The GOTHIC face is constructed of strokes of equal or near equal widths. Gothic letters do not have serifs and are sometimes referred to as block letters.

The gothic face has the same structure as the basic face. Gothic faces can be bold, medium, or lightface; they can be condensed, normal, or extended, and can be italic.

There are many uses for the gothic faces. They are excellent when bold impact is desired because they can be made extremely heavy or condensed without becoming difficult to read. In contrast, the light face gothic can be used to express great delicacy and restraint.

When drawing gothic letters, the chisel point must be turned in the direction of the stroke ensuring the same width of letter throughout its construction, as shown in figure 9-13.

As you can see, this is quite a different procedure than the one used in making the thick and thin roman face.

When drawing the gothic face, follow the same steps of procedure as done in figure 9-11 Use the T-square as a guide for making the verticals and horizontals. Draw the curved strokes freehand.

When doing gothic lettering strictly by freehand, rule vertical guidelines on your final run through. These guidelines showing through the visualizing paper will help you keep your vertical strokes uniform.

The curved stroke is generally drawn thinner where it joins the straight stroke, otherwise, a dark spot develops where the two heavy strokes join. Figure 9-14 shows a variation of the gothic face.

Figure 9-14.—Headline gothic.

10052

Figure 9-15.—Script lettering.

SCRIPT LETTERS

SCRIPT letters are based on our handwriting style. To get the feel of the basic strokes, it is best to write with a flexible pen that will make hairline strokes when light pressure is applied, and wide strokes when heavy pressure is applied.

There are many styles of script, but we shall concentrate on just two styles, the BASIC script and the FORMAL script; thick and thin versions are shown in figure 9-15.

Formal script gives the impression of elegance, dignity, and refinement, and is very easy to read. With a good understanding of the Basic and Formal script, you will be able to create many variations of script, and thus meet the many requests for this type of lettering.

Figure 9-16.—Constructing script lettering.

Hairlines which sweep up to join main stems are called kerns, and must be uniform in direction. They should all join the main stems at exactly the same height as pointed out by letter a in figure 9-15. For good spacing, the width of the curves made by the upsweep hairlines should be uniform.

There are three ways to properly construct script letters with the pencil. These are shown in figure 9-16.

Figure 9-16a shows the most accurate way to build up the thick strokes with a pencil.

Figure 9-16b shows a very quick way to indicate small script. As the strokes are drawn, heavy pressure is applied to make the thick lines, and very light pressure is applied to make the hairlines.

Figure 9-16c shows the third method, a useful and quick way to make large letters. The thick strokes are rendered with a chisel point and the hairlines are made with either the corner of a chisel point or with a pointed pencil.

Figure 9-17.—Text face.

TEXT LETTERS

You may know this face simply as OLD ENGLISH. Text was among the first face styles used in printing because Gutenberg (inventor of the printing press) worked almost exclusively with this style of letter. Although it is still used frequently, it is generally limited to a few lines of copy. It should be reserved for something religious or formal, such as prayer books, programs, invitations or other similar purposes. Figure 9-17 shows the basic construction of text.

DISTORTIONS AND OPTICAL ILLUSIONS IN LETTERING

The eye is often bothered by certain distorting effects that occur in lettering designs. Many of

SCOOL 10053

Figure 9-18.—Optical illusions.

these effects are of great concern to us, especially the illusion that makes certain forms of the same height appear quite different in height when placed beside each other.

A good example is when triangles, circles, and rectangles of the same height are placed together. The triangles and circles never look as tall as the rectangles. When you draw or design letters with these shapes, you must make corrections so that these disturbing effects are offset and your letters appear correct and consistent.

In figure 9-18 we see a triangle, a rectangle and a circle of exactly the same height. Due to an optical illusion, however, the triangle and the circle look shorter than the rectangle. To correct this illusion and make all three appear to be of the same height, the point of the triangle is extended above the guideline while the circle is extended beyond both the top and bottom guidelines.

Using the letter A to represent the triangle, the letter E the rectangle, and the letter O the circle, we can see that the letters A and O must be enlarged in order for all the letters to appear to have the same height.

The same considerations apply to the lowercase letters and similar adjustments are necessary in every face if the letters are to appear uniform in height.

When drawing the gothic faces, the heavy strokes that join other strokes must be thinned down to avoid the effect of these strokes appearing even bigger than they actually are. This is true in both the caps and the lowercase of this face. Figure 9-19 shows the correct method to make these adjustments. Though slight, these changes are very important to the proper construction of this face.

Figure 9-19.—Adjustments to letters.

OVERLAPPING LETTERS

When designing overlapping letters, care must be taken that they are not overlapped to such an extent that their form or their negative space is greatly distorted. The letters in figure 9-20 are properly overlapped because there is enough of each letter remaining so that your eye

Figure 9-20.—Overlapping letters.

can fill in the missing parts. Also, the identifying negative spaces have not been destroyed, as you can easily see in figure 9-20 by the blackest areas around the letters.

IDENTIFYING AND DRAWING THE DIFFERENT TYPE FACES

The different type faces can be identified by their serifs, their thick and thin strokes, their curves and their general silhouette. Once you have learned the identifying features of a few key characters of any face, you will be able to readily recognize the face and will know what characteristics and features to look for and stress when drawing the letter.

Figure 9-21 shows the comparison of the six main classes of type. Study the basic differences carefully and memorize those features which are related solely to one particular face.

ROMAN

Roman faces are often divided into two classifications: modern and oldstyle. The chief difference between the two is found in the construction of the serifs. Compare the two letters shown in figure 9-22. You will notice that the oldstyle letter has soft, rounded serifs, while the

10054

Figure 9-21.—Six main classes of type.

Figure 9-22.—Old and modern Roman face.

modern letter has heavier shadings and thin, clean-cut hairlines. Bodoni is typical of the modern style and Caslon is a good example of the oldstyle. Roman faces can be used for a variety of work, but printers try to avoid mixing the oldstyle with the modern faces. Figure 9-23 shows a few of the roman type faces.

GOTHIC

Figure 9-24 shows a few of the gothic type faces. Many of these faces are drawn or constructed in italics. The sans-serif included in the illustration is an up-to-date style of gothic. However, because of its modern design, it is generally grouped with the contemporary type faces.

As you can well see in figure 9-24, there are many kinds of gothic type faces. Each has its place in modern printing and lettering. Alternate and Copperplate Gothics have a wide use in Standard Navy forms. Copperplate Gothic is

generally used for letterheads, envelopes, cards, announcements and many other kinds of office forms.

News Gothic is another serviceable face. It may be used as a body type for titles and headings. Franklin Gothic, Alternate Gothic, and Poster Gothic are chiefly used for display work. They are very popular for posters and headings.

SCRIPT

Script faces are extremely suitable for announcements and invitations. They may also be used to impart an air of elegance and charm in displays. Figure 9-25 shows a few script type faces. You will notice that some of the faces shown are contemporary styles used in modern display work.

ITALICS

There is an italic style for nearly every roman, gothic and contemporary type style in use. Since italic lettering is hard to read when set in lengthy articles, the practice has been to use italics only to show emphasis or to create a contrast in the lettering. Figure 9-27 shows some of the italics in use today.

CONTEMPORARY

The past 30 to 40 years have been truely significant in lettering and typographic history. The

10056

old gothics have had their faces lifted and everywhere new streamlined faces have appeared. Naturally many of these modern faces are fads. Their style and usefulness will be short-lived. Out of it all, however, have come a few serviceable type faces that will take their places alongside the old standbys we have just discussed.

Leading the contemporary field are two distinctly new styles: the sans serif and the square serif.

Sans Serif

Sans serif is actually a kind of gothic type. It has the same even strokes as gothic and it has no serifs. But, unlike its gothic ancestors, it has such perfect geometric propostions that it is generally classified with the contemporary type faces.

Study the Futura type faces shown in figure 9-28 for a moment. Notice that the letters seem to be constructed from squares, rectangles and other geometric forms. This type face is the last word in simplicity, yet it is one of the most serviceable of all the type faces the modern printer and illustrator has at his disposal. It can be used for almost any printing or lettering job.

Square Serif

Square serif is little more than sans serif with serifs added. It has the same even strokes and the same perfect geometric proportions. Square serif type originated in Europe shortly after the sans serif faces made their appearance. It became popular in the United States in the early 1930s. Some people think it is an offspring of the old Egyptian alphabet. Others believe it was inspired by typewriter type which was widely employed by advertisers of that period. As you can see in figure 9-29, Stymie is a typical example of this type.

Figure 12-29.—A typical line-pulsing modulator and magnetron circuit.

When this point is reached, the rate of charge decreases rapidly, and the magnetic field around the choke collapses. By self-inductance, a voltage approximately equal to twice the power supply peak voltage is rapidly established. The resonant charging choke has an inherent tendency to oscillate, but this tendency is halted abruptly at its first positive peak by the rectifying action of the charging diode. The PFN is held at this high potential. Discharge of the PFN capacitors is prevented by the charging diode V2. The inverse diode and the thyratron are inoperative; hence they appear as infinite impedances and do not provide a discharge path for the network.

The master trigger generator in the synchronizer unit supplies a trigger voltage to the grid of the thyratron through the d-c blocking capacitor C1. When triggered, the tube ionizes and provides a closed circuit for discharging the PFN. Discharge continues for a definite period of time, at a rate determined by the constants of the PFN. A negative square shaped pulse is impressed across the primary winding of the magnetron pulse transformer. The width of the transmitter pulse varies in a manner determined by the number of sections of the PFN in use at the time.

Since the primary of transformer T2 is matched with the surge or characteristic impedance of the PFN, there is an equal division of voltage between these two units. The power supply peak voltage is impressed on the primary, and the turns ratio of the transformer results in a voltage step-up; thus a negative pulse of much greater magnitude is impressed

1003

Contemporary display faces is a classification which includes hundreds of modern type faces used in display work today. There are so many of them, that it would be difficult to try to list them all. There a number of scripts and italics, for example, which can be identified by their streamlined appearance. The Kaufman shown in figure 9-25 is one of these modern scripts. Others include Brush and Gillies Gothic.

There are also a number of tall, thin types, such as Onyx and Spire. Then there are wide, bold faces, such as Broadway and Neon. And, in between, there are medium faces, such as Lydian and Goudy Hand-Tooled. These types are used chiefly for display composition and some are shown in figure 9-30. More coverage is given this style under the topics of broad pen lettering and creative lettering.

FINISHED LETTERING

So far in this chapter you have learned the construction of the six basic faces. Now you will learn the proper procedure used to carry your work to its final stage, the finished lettering ready for reproduction.

The tools and materials needed to do finished lettering include a good pen with a flexible point and a pen with a very rigid point. Flexible pens should be used only on a hard surface paper, otherwise, the pen may catch on the paper and cause rough edges. A penholder of about the same thickness as a pencil will be the easiest to work with. A good ruling pen or a good Rapidograph pen is a must. A good quality No. 2 or No. 3 red sable brush is needed for retouching; when retouching, use a good opaque white.

Finished lettering is usually done on kid-finished Strathmore Bristol Board, or on a paper of like quality. Many kinds of paper are available; experiment and find the one that is most suitable to your needs.

Finished lettering is usually drawn one-half larger than reproduction size. Some illustrators prefer to enlarge the lettering to twice the size, Figure 9-31. Step one is to scale up your layout lettering. The easiest and fastest way is to use proportional dividers or a projector.

Adjust the dividers so that it gives a ratio of 1:2 or to whatever proportions you desire.

Now place your scaled up lettering under the top sheet of visualizing paper. Using a chisel point, or a B or 2B pencil, stroke in the letters until you have the correct weight and proportions for the letters. You can, by sliding the under tracing back and forth, align the letters as you want them. Check your lettering to see that the spacing and weight of the letters are uniform; if not, make another tracing. You may have to make several tracings before you have a satisfactory piece of lettering. Looking at the line of lettering from the back of the visualizing paper often shows up mistakes not otherwise noticeable.

Now do a final tracing. By building up your letters freehand, you can see what adjustments are needed, if any, in the width of spacing of the letters. You should have eliminated every problem of design on this tracing.

Turn your tracing over and blacken the back of it with an H or 1H pencil. This will give you a clean, firm, light line tracing when drawn. Attach the paper for your finished lettering to your drawing board. Tape the tracing to the top of the

Figure 9-31.—A method of enlarging lettering

drawing paper and, with a T-square, make two sets of register marks. Now you will be able to remove your tracing anytime you wish and still be able to correctly align it to your drawing paper.

With a 3H or harder pencil, a T-square and a triangle, trace all of the horizontal and vertical lines. Now loosen the drawing paper from the board, with the tracing paper still attached to it and turn the paper to whatever angle you desire and trace in the curves freehand. Always keep your pencil sharp while you work.

Frequently lift your tracing paper to avoid missing any lines, and to see if your transfer lines are sharp. You must make firm lines, but do not apply pressure so hard that you make furrows in the paper.

Remove the tracing from the finish sheet and with your pen, T-square, and triangle, ink all of the horizontal and vertical outlines.

Arrange your paper as before in the direction you most prefer and ink in the curved lines, using short strokes. Draw the edges smooth and sharp. They must be consistent with the edges of the horizontals and verticals. Keep your pen clean by wiping it frequently on a cloth or on scrap paper. This aids the ink to flow freely.

Do not correct any mistakes until you are completely finished with the job. If the ink has gone over the proper limits of a letter, use white opaque to cut it back. Any large corrections in black should be made with lampblack rather than india ink which may chip off of the large areas.

With an artgum eraser, carefully and gently erase any pencil marks or smudges. Examine your finished job carefully and make any final corrections or even up any ragged edges with a very fine brush.

BROAD-PEN LETTERING

Until printing was invented, all books had to be lettered by hand and the tool most often used was a broad flat pen. This broad-pen lettering continues to be useful in this modern era where the artist is required to do such work as posters, signs, certificates, charts, displays and countless other areas of freehand lettering work.

The broad-pen is a highly creative tool because of the various pen points available to choose from. A wide variety of novel and exciting lettering effects can be created with the broad-pen style of lettering. The term "broad-pen" includes the use of brushes because they can be used in the same manner as the pens.

To select the proper pen width for the lettering size desired, the rule of five times the width of the nib of the pen for lowercase letters and eight times the width of the nib for the caps is most often used by professional illustrators.

When using a broad-pen, light but firm pressure is all that is needed for the ink to flow freely. It is possible to draw many letters without lifting the pen from the paper because a good pen will work well regardless of which direction it is pushed or pulled.

MAKING BRUSH SCRIPT

Recalling the discussion on script lettering, you are now going to learn a more casual, spontaneous version of script: brush script. Brush script has a unique freshness, bounce and vitality and is widely used. You will have to try many different styles of writing with the brush to achieve the effect you want. To practice this style of lettering, you will need a bottle of ink, a supply of paper and a No. 2, No. 3 or No. 4 sable brush. Figure 9-32 shows the usual three to five steps taken to do brush script.

Step 1: Write the copy over and over until you get the desired effect.

Step 2: Select the word or parts of words or letters which you feel has the character of the style you are seeking. The parts you select should be easy to read, consistent in character, size and weight.

Step 3: Cut out the sections you have selected. Paste them down with rubber cement. Before the cement dries, you can move the sections around to get the proper spacing and alignment. Clean away any surplus cement and make any additions or adjustments with brush and ink.

Step 4: When you want a more exacting job, you can make a negative, paint out the section lines, and make any final changes you find necessary.

Step 5: Have a glossy positive made from the retouched negative. This will be the finished art. If necessary, you can still make improvements directly on the photostatic positive.

BRUSH GOTHIC

The procedure just covered can also be used to make the animated styles of separated letters

10059

often called brush gothic. You can create an almost unlimited variety of letters with this technique.

Forget about guidelines when drawing the casual animated letters, but keep in mind that your letters should always be of uniform height.

When drawing light letters, your brush should be pointed; use very little ink. Hold the brush almost vertical to the paper and allow only the point to touch the paper.

When drawing heavy letters, a worn or blunt pointed brush, or one with the tip cut away is best. Load the brush with ink and hold it at a close angle to the paper. This will make a wide stroke.

With proper practice, you will be able to create a wide variety of letters using both brush script and brush gothic as formats.

SHOW-CARD LETTERING

Show-card lettering is often referred to as "show-card writing," for an experienced letterer of show-cards is so skillful and fast that he seems to literally write his signs.

Show-cards are varied in their requirements. This will afford you ample opportunity to experiment with the designs of the different kinds of letters and layouts. This experimentation is an excellent way for you to develop and apply your ability to create new lettering forms and effects.

There are two favorite types of brushes preferred for show-card lettering. They are the rigger brush, a red sable brush with a round ferrule available in sizes from a No. 1 (very small) to a No. 12 (large), and the single stroke red sable brush with a flat ferrule which comes in varying widths from 1/8 of an inch to 1 1/2 inches. After using these brushes, wash them thoroughly and dry them with a dry rag.

Paper for show-card lettering comes in a great variety of surfaces. One of the most commonly used is a white cardboard which is available in 22 x 28-inch sheets, 30 x 40-inch sheets, and 28 x 44-inch sheets. It is also available in a wide variety of colors. Rolls of 10 to 100 yards in length are available for doing large signs or banners.

The pen most commonly used is the Speedball and it comes in a wide variety of pen tips, including round, square, oblong, and oval.

Show-card paints, often referred to as poster paints, come in a wide variety of colors and sizes. These paints often dry out as moisture evaporates when the lids are not kept tight. Water can be added to bring the paint back to its proper consistency. For use in lettering pens, the paint can be diluted, or ink, especially made for lettering pens, can be used.

Gothic or variations of gothic faces are the most widely used style of letters in show-card lettering. The brush is first dipped into the paint, then worked to a chisel point before it is applied to the drawing surface. The hand movement is kept free; the actions of the fingers, wrist and arm move, keeping the strokes flowing freely at all times.

Figure 9-33 shows how the vertical and curved brush letters are made.

Step 1: Draw the vertical strokes.

Step 2: Turn the brush sideways and square off the top and bottom of the vertical strokes.

Step 3: Make the left half of the curve. Hold the ferrule of the brush between the thumb and forefinger, and twirl the brush in the motion indicated by the arrow in the illustration.

Step 4: Connect the curve as needed to finish the letter.

CREATIVE LETTERING

As an Illustrator Draftsman, your imagination and sensitivity to the design of lettering should be as free as that of the commercial artist. You may not have the opportunity to do fashion layouts using the delicate lettering on a feminine subject, but you must have the ability to create a delicate style of lettering in the event you are ever called upon to do so.

You will most often be striving to create a coarse, heavy lettering, one which expresses a strong, dramatic theme of action, heroics, and all the other actions signifying the Navy as a man's organization. In creating this dramatic style of lettering, your first concern should be that your letters fully express the mood and character of the subject matter.

Your lettering should also be related to the other design elements of the layout or provide a contrast or a relief from the other elements. More often than not your decision as to style will be aided by your leading petty officer or the originator of the job itself.

Figure 9-34 gives a few examples of how words can be treated. As an Illustrator Draftsman, you will have much creative freedom in approaching most of your lettering assignments. This does not mean, however, that you are to lessen the emphasis that has been placed on the

0300 10661

Figure 9-34.—Creative lettering.

need of your thoroughly understanding the fundamental letter forms, or the principles of correct letter, word, and line spacing.

Before you take any creative liberties in lettering, you must have a complete understanding of the basic fundamentals that have been provided. Success will not come until you do.

LETTERING GUIDES

Lettering guides, such as Leroy and Wrico sets, have the advantage of ensuring that letters and figures made with them will be absolutely uniform. By using these guides instead of working freehand, you can do lettering which is more professional in appearance. However, even someone who has developed maximum skill in the use of these guides cannot letter as rapidly as a proficient freehand letterer. Also, when you use these lettering guides, you must still determine the spacing between letters and words. Remember that a line of lettering will not look professional unless it is properly spaced.

LEROY LETTERING SET

In addition to the case, Leroy lettering sets consist of five components parts: a number of guides or templates in which the lines of the letters are indented, a three-legged scriber, a number of inking pens of varying sizes with cleaning pins, a penholder with a special Leroy penholding attachment and a special penciling attachment for the scriber. Figure 9-35 shows the scriber and the template in working position. The legends name the various parts.

One leg of the scriber holds the pen or pencil, and the other two legs terminate in tracer points. One tracer point or tail pin moves in a long, straight groove on the template. The other moves in the depressed letters on the template. When this latter point is moved around the contour of a letter, the entire scriber hinges on the tail pin in the groove and the pen or pencil traces the letter on the drawing paper.

Alongside the penpoint, there is a rest, adjustable in height, which prevents the pen from resting heavily on the drawing. This must be carefully adjusted because the pen will make a satisfactory line only when it is in very light contact with the drawing. You should experiment to find the exact point to adjustment.

The pens are vertical, with a reservoir for ink, and have a steel wire or cleaning pin running down into the opening at the bottom to keep the ink from clotting in the point. The pens are held in the scriber by means of a clamping screw.

In straight-line lettering, the spacing between letters can be determined by the eye before inking each succeeding letter. The space-area between all letters of a word are to be made equivalent; that is, in order that the word may have the appearance of having uniformly spaced letters, the areas between the letters, rather than the distances between them, must be made about equal as in figure 9-36. The area between adjacent letters depends upon the shape of the letters. Straight-sided letters such as H and I, I and K, M and N, or N and B, are drawn farther apart than round letters like O and Q, O and C, or C and G, and slant-sided letters in combination with open letters such as A and L, L and A, or V and J, are drawn with less space between them than the round letters. Where letters such as L and T, L and V, or A and V come together, they may have to overlap in

Figure 9-35.—The Leroy scriber and its operation.

order that the word does not appear to be broken into two or more words.

As in freehand lettering, the space between words should be made about equal to either the width or height of the letters, and the succeeding words should be drawn at the same spacing.

When lettering has to be centered above a certain part of a drawing or within the center of a certain space, the scales along the bottom edges of the templates aid in the centering of a

Figure 9-36.—Spacing.

line of lettering. Each space on the scale represents the center-to-center distance of normal-width letters. For example, to center the words "LEROY LETTERING" above a certain line, proceed as follows:

1. Count the letters in the words and the words and the spaces between them. Result: 15.

2. Considering the letter "I" and the spaces between the words as half value each, reduce the total by one (1). Result: 14.

(NOTE: If there are an odd number of half values, take the next lower even number and allow more space between words than normally required.)

3. Divide the result of No. 2 above by 2. Result: 7.

4. Set the zero of the scale at the vertical line about which the lettering is to be centered and mark off seven spaces to the left and right of zero.

5. Start the "L" of the word "LEROY" in the title at the left mark and continue to the end. The right edge of the "G" should fall on the mark to the right.

Vertical lettering should be used whenever possible when lettering along a curved line. The axes of the letters should be coincident with the radii of the curves through the center of the letters. When slant lettering is required, the letters are drawn so that the radii of the curves run through the center of the bottom of the letters. Since the axes of the letters will not be parallel, a straightedge need not be used. The fastest and best way to accomplish lettering on curved lines is to proceed as follows:

1. At the position where the letters are to be drawn, sketch a light pencil line parallel to the given curve for the bottom or top of the lettering.

2. By visual inspection, determine the direction of the radial line through the center of the letter.

3. Place the Leroy template on the drawing so that its edge is perpendicular to the radial line.

4. Insert the tail pin of the scriber in the straight-guide groove of the template, and the tracer pin at the bottom or top of the required letter.

5. Move the template and scriber as a unit to the left or right and up or down as required, keeping the template parallel to its original position, until the tip of the pen is at the correct position.

6. Trace the character.

7. Repeat the preceding steps until the lettering is completed, effecting equivalent spacing between succeeding letters and words.

(NOTE: If the degree of the curve is known and a template of that degree is available, it may be used to guide the Leroy template.)

Any drawing can be neatly completed with lettering of uniform slant, height, and thickness of strokes with the use of the Leroy set by taking the following steps:

1. Select the template with the letters of the desired height.

2. Lay the template along the top of a T-square or the straightedge of a drafting machine.

3. Using the table shown in figure 9-37, select the proper pen to give a well proportioned letter.

On drawings with a great deal of lettering, the recommended combinations may be altered, either one pen-size under or over the recommended size for variation and appearance.

4. Insert the selected pen into the socket of the scriber arm until the shoulder of the pen rests on the scriber arm.

Figure 9-37.—Table for selection of proper Leroy pen.

10063

5. Tighten the screw on the side of the scriber arm.

6. Loosen the locknut on the adjusting screw in the scriber arm.

7. Set the tail pin of the scriber in the straight guide groove of the template.

8. Set the tracer pin of the scriber in the groove of a character.

9. Lower the pen gently to the surface of the drawing paper.

10. Raise or lower the scriber arm by turning the adjusting screw until the tip of the cleaning pin within the pen just touches the drawing surface. Tighten the locknut when the desired height is reached.
(NOTE: To prevent blotting, this adjustment is made before ink is put into the pen.)

11. Remove the scriber from the template.

12. Remove the cleaning pin from the pen.
(NOTE: When using Leroy pens No. 4 and larger, the cleaning pin should not be removed from the pen. This prevents the ink from flowing straight through the pen.)

13. Fill the reservoir of the pen with drawing ink.
(NOTE: The Leroy pen is filled with ink in the same manner as any common drafting inking instrument.)

14. If the cleaning pin was removed, insert it back into the pen.

15. Wipe the lower tip of the pen with a cloth to remove any excess ink that may have been pushed through by the cleaning pin.

16. Gently lower the pen to the drawing surface after inserting the tail and tracer pins into their proper grooves.

17. Proceed with the lettering by moving the tracer pin in the grooves of the characters, keeping the tail pin in the straight-guide groove.
(NOTE: If the ink does not flow properly, turn the cleaning pin within the pen, and make any minor adjustment to the adjusting screw to allow the ink to flow properly. Tighten the locknut. It is suggested that during short intervals of nonuse that occur when lettering, that the tip of the pen, while still in the socket of the scriber arm, be placed on a piece of moist cotton. This will prevent the ink from drying around the opening and will help the ink to flow properly when used again. To also prevent drying of the ink at the tips of the pen, wipe them frequently while lettering. A clean tip will produce strokes of uniform width.)

Wash each pen carefully after it has been used. Do not hold the pens under running water when you wash them, since they are so small they can easily be dropped down the drain. Use a syringe to rinse the pens if you have one. The manufacturer of the Leroy lettering set offers a special pen-cleaning fluid which is excellent for washing pens or for soaking off dried ink.

WRICO LETTERING SET

The Wrico lettering set contains a vertical penholder for various penpoints and a number of templates. Each template contains a number of differently shaped perforations from which letters in one size and style can be stenciled.

When you use the Wrico lettering set, align the bottom of the letter shapes in the template with the bottom guideline on your paper, resting the template against a straightedge. Since you will need to slide the template back and forth to draw different letters, it is a good idea to tape the straightedge in place. A shift button is provided at the right end of the template to make it easier to shift from one perforation to another when two must be used for a single letter shape. Be certain an ink line is dry before you shift the template, otherwise you may smear the ink.

The Wrico pen is vertical with a reservoir for ink. It is equipped with a plunger which keeps the point of the pen from becoming clogged with drying ink. For maximum performance, the Wrico pen should be kept clean. However, it is not a good practice to leave the pen soaking in water or a solution when it is not in use.

VARIGRAPH

The Varigraph, shown in figure 9-38 is another mechanical lettering device that operates with template and scriber. There are two sets of adjustments on the varigraph which permit the user to adjust height and slant of the lettering while using one template. There are no templates of varying sizes as with the Leroy or Wrico lettering sets.

MECHANICAL AIDS FOR LETTERING

HEADLINER

An Illustrator Draftsman may be called upon to use a photographic process lettering machine such as the Headliner. The Headliner produces positive copies on 35 mm film or on 35 mm plastic finished paper. The processing is

C.3 [illegible] 16065

Figure 9-38.—Varigraph.

similar for both the film and the paper. The films may be used in preparing transparencies for reproduction on diazo foil transparencies. Since paper positives are generally preferred for design paste-up purposes, this discussion will center on them.

The type master, letter (Q) in figure 9-39B consists of a plastic disk with transparent (reverse) characters. Many type faces are available in sizes from 12 to 72 point, but a separate disk must be used for each size and style. This disk fits on a turntable located just under the top of the machine, also indicated by letter (Q) in figure 9-39B. The movement of the turntable is synchronized with the movement of the knob (J). (See fig. 9-39A). Turn the knob to move the desired character under the indicator (F), and then make the exposure by pressing the print bar (B).

The proportional spacing of the letters is controlled by the depth of slots cut for each letter in the edge of the type disk. There are deep grooves for wide letters like "M" and "W" and shallow grooves for narrow letters like "j" and "i."

To space between words, press the space bar (C). The word spacing knob (L) is used to adjust the spacing between words. To set the spacing, turn this knob until the reading on dial (M) corresponds to the point size of the type being used. You can adjust the machine for closer or wider spacing between the letters in the words by turning the spacing knob (K) to move dial (N).

When you have finished a line, turn the paper advance knob (G) forward three or four revolutions. This moves the photographic tape forward and allows for plenty of space between the end of one line and the beginning of the next.

The line length indicator (D) shows the amount of paper that has been used in setting the line. The automatic developing mechanism will not work unless at least 8 inches of paper have been advanced into the machine. Turn this dial manually to zero before beginning a new line.

Once the line has been set and the paper has been advanced properly, raise lever (S) see figure 9-39C and do not release it until a red light comes on at the front of the machine. This lever cuts the paper and starts it through the automatic developing unit. Developing operations are entirely automatic. The tape is carried first through a developing solution; then through a fixing solution; and finally, through plain water before it is forced from the machine.

The finished print should be dried before being used. Sanding the glossy covering from the back of the tape makes it adhere better when used with rubber cement.

Since the emulsion on the 35 mm tape is fairly slow, the tape can be handled safely for short periods of time in moderately bright light. However, if the light is too bright or the light source too close the tape may fog or turn gray. The use of a yellow or a red light during loading and threading operations will ensure relative safety.

Since the width of letters vary from one type style to another, it is necessary to adjust the lighthouse opening by moving the lever (P) when switching from a small to a large type face and vice versa. The setting for the lighthouse is printed on each type master. The exposure time can be adjusted if necessary by turning the knob (T).

The machine shown in figure 9-39A prints only one line of type on the tape. The Multi-Line model shown in figure 9-40 will produce one, two, or three lines of copy on the tape depending on the type master used. To produce three lines of copy, it is necessary to use a master with three rows of characters. You adjust the opening in the lighthouse so that only the characters in the top row will be exposed when the first line is printed, then turn the paper back to the starting point, reset lighthouse opening and print the second line. Repeat this same procedure for the third line.

10065

A. Space lever. Set at full font if type and lower case letters are on same type master; set at half font if caps are on separate master.
B. Print key. Press down to make exposure.
C. Space key for spacing between words.
D. Line length indicator. Move to zero by hand when starting new line.
E. Switch.
F. Character indicator. Turn knob (J) to bring desired letter into position.
G. Paper advance knob. When plunger (H) is pulled out, line length indicator will register, but paper will not advance in machine.
H. Plunger.
J. Knob used for turning type master to bring desired letters into position under indicator (F).
K. Knob for adjusting spacing between letters in word.
L. Wordspacing knob used to adjust spacing between words.
M. Wordspacing dial. To set, turn knob (L).
N. Letterspacing dial. To set, turn knob (K).

9-39A.—The Headliner.

10068

9-39B.—The typemaster.

O. Lighthouse. Raise when changing type master.
P. Lever for setting lighthouse opening. Set according to width of letter. (Setting for each type style is marked on type master.)
Q. Type master. The apertures in the disk fit over pins on a turntable that is synchronized with knob (J), shown in figure 9-39A.
R. Paper or film supply.

9-39C.—Operating controls on left side of headliner.

S. Lever. Raise to cut photographic tape or film and start it through developing unit. If lever will not lift; do not force it. Check to see if at least 8 inches of tape has been advanced in the machine.
T. Knob for adjusting length of exposure.

Since larger type faces require more space than the smaller ones, it is not possible to make more than one or two lines when these large faces are used. In some cases, it is also necessary to use two type masters; one for the lowercase, and one for the caps. When two masters are used, lever (A), figure 9-39A is moved to the half-font position.

Except for the multi-line feature, the operation of the model shown in figure 9-40 is similar to the one shown in figure 9-39A.

LETTERING ON NAVY DRAWINGS

In the Navy, single-stroke commercial gothic lettering is used on construction and production drawings. Inclined lettering and vertical lettering should not be used on the same drawing. Lowercase letters are never used on production drawings. However, lowercase letters may be used on construction drawings except in titles which should always be lettered with capitals. These rules, of course, do not apply to the lettering on illustrations which appear in publications.

Lettering on maps and charts is ordinarily quite different from the lettering on engineering drawings—mechanical, electrical, or structural. Instead of being hand lettered, such lettering is often type-set and the reproduction proofs pasted in place on a map or overlay. The lettering on maps and charts is discussed later.

10067

on the cathode of the magnetron. The peak power of this pulse is quite high, although the output of the magnetron is somewhat less, due to losses in the tube and associated circuitry.

Gas bursts (arcing) occur occasionally within the magnetron. This condition causes a momentary impedance mismatch. A small voltage of a polarity opposite to that of the modulator pulse appears across the PFN when arcing occurs. This small reverse voltage is in series with the power supply voltage at the start of the next charging cycle; hence the total voltage available to produce the charging oscillation is increased. The pulse line voltage may build up to a value great enough to break down the thyratron. This possibility is overcome by connecting V3 in paralled with the thyratron. The diode bypasses the reversed charge of the PFN.

The PFN is composed of aircore inductors and mica capacitors. It is divided into three sections of artificial transmission line, all within the same container. Each part is a complete network. The connection of the three parts (by relays K1 and K2) increases the width of the pulse. During BEACON operation, only the beacon pulse relay K1 is energized; thus the A and B sections of Z1 are connected in the circuit, providing a pulse of longer duration than that previously obtained. During long range search operation, both relays are energized; thus all three sections of Z1 are connected in the circuit to provide a still longer pulse.

Resonant charging choke L1 not only doubles the pulse system voltage before firing, but it effectively isolates the power supply from the rest of the modulator during the relatively short periods of pulse duration. It also prevents the power supply from shorting through the switch tube during de-ionization.

Resistor R1 functions as a grid leak for the thyratron switch tube. Capacitor C2 and choke L2 form a filter network to prevent reflection of the switch tube transients into the synchronizer. Switch tube current, flowing through the cathode resistor R2, generates a trigger pulse which may be used for synchronizing the rangemark start-stop multivibrator (located in the synchronizer unit). Resistor R3 and capacitor C3 improve the trigger shape by removing ripple at the top of the pulse.

The cathode of the magnetron is internally connected to one side of the filament line. Input to the magnetron is supplied by the modulator through the magnetron pulse transformer. Design of the pulse transformer provides two secondary windings of similar electrical characteristics, one in each leg of the magnetron filament supply. This "bifilar" secondary winding maintains an equal and in-phase voltage on both sides of the filament, effectively isolating the high voltage modulator pulse from the low voltage magnetron filament transformer. Capacitors C4 and C5 compensate for slight electrical differences between the output windings of the pulse transformer, preventing the appearance of high pulse voltages across the filament.

The d-c plate current of the magnetron flows from ground through R4, L3, and secondary winding of the pulse transformer, the cathode circuit, and the plate circuit back to ground. Coil L3 blocks peak pulses, but passes average current through the magnetron current meter. Capacitor C6 offers a low impedance to the magnetron pulses and integrates them for metering. Negligible current is generated within the magnetron during quiescence (nonoperation), but the average (or d-c) current summed over a long period of pulsed operation is of high magnitude. Longer pulse periods at a lower PRF tent to balance shorter pulse periods at a higher PRF; the result is a nearly uniform duty cycle, regardless of the radar function being performed. While 115 volts is applied to the magnetron filament transformer during standby, it is reduced to 65 volts when the high voltage is applied to the modulator.

VELOCITY MODULATED TUBES AS LOCAL OSCILLATORS

Most radar receivers use an IF frequency of 30 or 60 mc, which is usually only a small fraction of the transmitter frequency; therefore, stability of the local oscillator is a prime factor in receiver operation. For example, in a radar receiver which receives a frequency of 3,000 mc, a frequency shift in the local oscillator as much as 0.1 percent would be a 3-mc frequency shift. This is equal to the bandwidth in most receivers and would cause a considerable loss of amplification in the receiver.

Another consideration in radar is a receiver which uses a crystal diode mixer. In this receiver the power required of the local oscillator is small, being only 20 to 50 milliwatts

1004

Figure 9-40.—Multi-line model headliner.

RECOMMENDED SIZES OF LETTERS

Because many mechanical drawings are now reduced to a small size when they are reproduced, or are photographed on microfilm and then enlarged, the lettering on drawings must be large enough to remain legible. MIL-STD-1B, 9 July 1963, shows the effect of reduction of lettering. See figure 9-41.

In the absence of factors making larger lettering desirable, the following sizes (shown in fig. 9-42) for lettering on Navy drawings are recommended.

When commercial lettering guides are used, sizes that correspond to the sizes given in figure 9-42 are acceptable. When typewriters or lettering machines are used, nothing smaller than the standard pica, or 12-point, type should be used.

REDUCTION GUIDE FOR LETTERING

CHART LETTERING

Lettering plays such an important role in the finish of charts and maps that the need for perfection in this element of their construction can hardly be overstressed. The lettering on a chart does much to establish the initial impression of the work. Slight imperfections that might not mar the symbols on a chart are quickly detected in the lettering.

There are several factors which enter into the production of superior lettering and topography. The aim must always be toward letters which are appropriate to the purpose. Type and lettering highly effective in advertising, book, or decorative work might be an unfortunate choice for serious charts and maps.

Letter styles on charts should be sufficiently restrained to avoid calling attention to their design. They must be legible, open enough to reproduce well by the lithographic process, yet not so bold as to kill adjacent type or to cause spottiness in the chart. They should blend in reasonable harmony when mixed.

Introducing types of widely divergent design, such as sans serif and roman, in a single work is unavoidable when clear-cut distinctions must be made among the various elements of a chart. To be considered for adoption, a style usually should be available in light, medium, and bold, with italics to match, but, this is not always possible. Different types which give similar effects may be used instead. Some good styles are not sufficiently economical of space to be practical for all work. Condensed or contracted forms must be resorted to and should be available.

10068

OCEANOGRAPHIC OFFICE CHARTS

Navy Department charts, including aeronautical charts and the charts in the Seaplane Pilot's Handbook or the Seaplane Route Manual, are produced at the Oceanographic Office. The lettering on aeronautical charts is similar to that on navigational charts, but the lettering on seaplane route charts is different in that only sans serif types are used.

The Oceanographic Office has established certain rules concerning lettering on charts. The purpose of these is chiefly to ensure the use of different types to indicate differing features. In the past, engraved lettering was used extensively. Now, however, only the figures for soundings, abbreviations for bottom characteristics, symbols, and standard notes are engraved. The size of these are indicated by a gage number which refers to the size of the stylus used by the engraver. Foundry type or monotype is used for other lettering.

Land features are shown in vertical lettering, and water features are shown in slanted lettering. Important features are shown in caps. Any feature larger than 12-point type is shown in caps. Place names are generally shown in full strength, that is, roman type. Descriptive notes and secondary names are set in sans serif type.

10069

CHAPTER 10

THE ILLUSTRATOR'S FOUR BASIC MEDIUMS

This chapter is essentially a handbook of four basic mediums: pencil, ink, ink washes, and opaque paints. The beginner is not expected to become a master technician with all or any one of these mediums at the start. However, during the span of your Navy career as an Illustrator Draftsman, you will often use these basic artist's tools and materials, so a thorough knowledge of them is a must if you are to become proficient in this rating.

PENCIL DRAWINGS

THE PENCIL

The pencil is the most valuable tool you will ever use as an Illustrator Draftsman. Regardless of what medium your drawings will be done in, you will do the planning with a pencil. The pencil is the most versatile of all drawing tools; you can create a range of values from the subtlest gray to the richest black, and create the thickest and thinnest lines. In addition, when you want to make a change to the preliminary drawing, the pencil lines can be erased.

Figure 10-1 shows 16 grades of pencils commonly used. Nine are hard: from H, slightly hard, to 9H, extremely hard. Six are soft: from B, moderately soft, to 6B, extremely soft. Between the two is a medium HB pencil. The softer the pencil, the thicker the lead and the broader the line drawn with it. Soft pencils need frequent sharpening, while the harder pencils retain their fine points for a longer time. When you are drawing and need a darker line, don't bear down on a hard pencil because this will cause grooves in the paper; instead, use a softer pencil to achieve the darker tone.

ERASERS

Of the erasers introduced in chapter 3, those most used by the illustrator are the kneaded eraser, the art gum eraser, and the flexible soft eraser.

The kneaded eraser picks up and absorbs pencil lead without leaving any rubber particles on the drawing. It can be molded to a point to clean the smallest area on your drawing and is especially good for bringing out highlights on pencil drawings. The kneaded eraser may be used to remove smudges without erasing the drawing by gently rubbing it over the drawing surface. Because it is soft, it will not erase heavily drawn lines.

Figure 10-1.—Grades of pencils.

10070

Figure 10-2.—Two ways of holding the pencil.

The art gum eraser is the favorite of most illustrators for cleaning a drawing after it is finished. It is especially good for removing pencil lines after a pen and ink or a brush and ink drawing is finished.

The flexible soft eraser is a rubber eraser similar to the one found on the end of a pencil. Its main purpose is to erase lines made with heavy pressure.

Erasing must be done slowly and carefully, using a gentle circular motion. Eraser particles from either the art gum eraser or the flexible soft eraser should be removed from the drawing surface with a small CLEAN desk brush.

HANDLING THE PENCIL

Hold your pencil comfortably and naturally. Grip the pencil lightly. When drawing light lines, press the pencil lightly; when drawing heavy lines, apply a little more pressure.

Figure 10-2 shows two ways of holding the pencil. Position #1 is good when drawing lines that must be carefully controlled and precise. Position #2 is good when working large areas such as outlines or shading in large areas.

CREATING VARIETY OF EFFECTS WITH PENCIL

Figure 10-3 shows a small portion of the many different effects and indicates the wide variety of movements possible with the pencil. These are not just doodlings. Practice of these movements will help to acquaint you thoroughly with the range of possibilities of this versatile tool.

THINKING IT OUT WITH A PENCIL

When you are planning a picture, you must put your thoughts down on paper. Small rough sketches done as easily and quickly as possible are best. The pencil is a thinking tool. With it you can speedily indicate the many ideas racing through your mind and then use combinations of these rough sketches to design your final picture. This way you can speedily create many different effects in a short amount of time.

Figure 10-4 shows how a final picture was created from many ideas roughed out in quick sketches.

INK DRAWINGS

Drawings made with pen and brush are called line drawings. With line drawings there are no grays, only solid black lines or black areas. Gray tones can be made by drawing many fine black lines close together giving a gray effect. The closer the lines are drawn, the darker the gray area will appear to be.

Figure 10-3.—Various movements possible with the pencil.

STOCK 10071 74
10030

A wide variety of lines can be created with the pen or brush, from a smooth line like the softness of a girl's cheek, to a rough line like the bark of a tree.

Moving the flexible pen across the paper, you can make a thin line by easing the pressure on the pen, or you can make a thicker line by applying more pressure to the pen, giving more variety and character to your line.

Line drawings are reproduced more easily and more inexpensively than any other type of drawing. They print well on all types of paper, where pencil, wash, or opaque drawings cannot. There is almost no limit to the uses for line drawings. So, throughout your career, your ability as a line artist will be one of your most valuable assets.

PEN AND INK

Pens

Pens are classified according to the thickness of the lines they form. A broad thick line is made with a coarse pen. A thinner line is made with a medium pen and a fine line is made with a fine pen. A crowquill pen is especially good for drawing very fine lines. Some pens are flexible, others are stiff. When a pen is flexible, a little pressure on it will result in a much broader line.

Many manufacturers make excellent pen points. Each of these manufacturers gives his pen points a different number. There is very little difference in the performance between two of the same style. There is also little difference in which brand you use; it is how you use it that counts.

Use a pen holder that feels comfortable. One that is about the same thickness as a pencil is preferred by most. A special holder is made for the smaller crowquill pen.

Ink

A black, opaque ink should be used. If the ink is too thin, it will look gray and not reproduce well. Light blue ink will not readily

Figure 10-4.—Creating a picture from rough sketches.

CT002 10072

reproduce on photo-lithographic Diazo equipment. A good waterproof ink will not run if you paint over it. Ink can be applied straight from the bottle. Ink will thicken and not flow properly if the top has not been kept well closed when not in use. If this happens, thin it with a few drops of water.

Using the Pen

When using a pen point, dampen it on your lips and wipe it dry. This often helps the point hold the ink and makes the ink flow better.

Never dip your pen too deep in the ink. You may pick up too much ink and it will blot and spoil your drawing. Whenever ink begins to cake on your pen, wipe it clean with a soft rag. You will find it beneficial to wash your pen points after using them.

Do not handicap yourself with defective or worn out pen points; replace them.

Pen Drawings

When making line drawings, you can draw your picture in pencil directly on the drawing paper and ink over the pencil lines, adding texture and tones as needed. After the ink has thoroughly dried, erase over the entire drawing with an art gum eraser to remove any pencil lines and smudges.

Figure 10-5.—Shows how a well planned pencil drawing is inked in.

Another method is to work out your drawing in pencil on tracing paper and then blacken the back of the tracing and transfer it to the drawing paper. Ink in and clean the picture the same as before. Figure 10-5 shows how a well planned pencil drawing is inked in.

Creating Textures with a Pen

You can create many varied effects with the different pen points. Figure 10-6 shows just a few of the many effects possible. Notice the length, width, and direction of the strokes and the amount of white space between them. When drawing crosshatched lines, you must let the first set dry before you cross them with the second set or the intersections will become large blobs of ink.

BRUSH AND INK

Brushes

The brush is soft and flexible, and answers to the slightest pressure. Any kind of line, from the lightest hairline to the widest rough heavy line, is readily available by using the brush. It is possible to make a drawing with the brush that only an expert could tell from pen drawings. Brush and ink drawings can be reproduced as easily and inexpensively as pen and ink drawings.

Brushes are available in a wide range of sizes, styles, and materials. Number 000 is the smallest brush and the brush sizes increase as the number increases.

Excellent all-around brush sizes for line drawings are the numbers 2, 3, 4, and 5. They will hold more ink than the smaller brushes, yet they can make a line almost as fine as the number 000. Too fine a line will not reproduce well.

Pointed sable water-color brushes are best for line drawings. The better ones will give better effects and last longer than the cheaper ones. A softer paper can be used than that which was used with the pen because the brush will not pick up the fibers and cause rough lines or blots. Black waterproof drawing ink is excellent for brush work.

Using the Brush

The same procedure used in pen and ink drawings is followed when making brush and ink drawings. Lightly trace lines from the

Figure 10-6.—Varied effects with the different pen points.

Figure 10-7.—Varieties of lines and effects possible with a brush.

preliminary sketches and ink directly over the lines. Use the brush to develop the lines and create line character. Always remove excess ink from the brush and stroke the brush on a piece of scrap paper before touching the brush to the drawing paper.

The brush is held in the same natural way you hold your pen or pencil. The brush is a sensitive, responsive tool and must be held lightly.

Always clean your brush with soap and water after each use. Once the brush is completely clean of ink, rinse it thoroughly and shape it before putting it away.

Figure 10-7 shows some of the varieties of lines and effects possible with a brush.

WASH DRAWINGS

A full range of values, from a solid black to the white of the paper is available with wash drawings. A wash may be used for every degree of finished drawing: from a flat decorative effect to a realism that is hard to distinguish from that of a three-dimensional photograph.

WASH

Wash is made by adding black pigment to water. The amount of white paper showing through determines the lightness of the tone. Add a relatively larger amount of water for light tones, less water for medium tones and very little water for dark tones. Pure black pigment should be used for solid blacks.

Water-color lampblack is the only pigment needed for wash drawings. Good round sable brushes should be used. The number 3 and number 5 are the brushes most frequently used, but one or two larger sized brushes should be available for occasional use. When doing large flat areas, a flat sable brush 3/8 or 1/2 inches wide is recommended. Wide brushes are also useful for moistening areas with clean water before painting. Good brushes well taken care of are a prime asset.

There are some specially made water-color papers available which will give the best results when doing wash on water-color work, but for a less expensive paper and one of reasonably good quality you will find that illustration board is the best general type of paper to use. It is available in three surfaces: smooth, medium, and rough. These are referred to as hot pressed, cold pressed, and rough.

WORKING IN WASH

As with pen and ink, the outlines of the picture are first drawn on the illustration board with an H, HB, or B pencil. With the kneaded eraser, remove any excess lead from the drawing surface.

Moisten the illustration board with clear water, using either a wad of cotton or a wide flat sable brush. Moistening the paper allows the wash to be applied without instant drying; instant drying is undesirable because it causes each stroke to become sharp and distinct. When there is no water reflecting from the paper's surface, it is dry enough to work on.

Again moisten that particular area you are painting in. Only practice will teach you how moist you will want the surface to be in order to create different effects.

Mix your washes. Always mix more tone than that which you think you will need because if you run short while you are working, you cannot stop and mix more wash to match the one you started with. When this happens, the tone will not be smooth and even on your paper.

If the wash area drys before you can cover it thoroughly, repeated applications will cause streaks and sharp edges, as stated before. Therefore, you should use as large a brush as possible to wash an area. This also helps to create a more even wash because the larger brush holds more wash and you will not have to stop to load the brush as often.

To load the brush, dip it into the wash. Gently press the brush on the side of the wash container so that about one drop of wash is expelled. This should make the brush just about right for painting.

Never attempt to paint a wash with a brush that is dry. You should have a piece of scrap illustration board of the same quality as the board you are painting on to test your brush on before applying it to the painting surface.

When you get the correct value of light or dark in an area with one wash, it will have more freshness than if you have to lay one tone over another to get the desired shade.

The three basic qualities of wash are: (1) it is transparent, (2) it blends natrually from one moist tone to another, and (3) the tones are built up from light to dark.

Figure 10-8.—Applying the wash.

FLAT AND GRADED WASHES

Painting a Flat Wash

Moisten the paper with clean water and allow time for the water to be absorbed into the paper until no water reflects from the paper's surface. The drawing board should be slightly tilted so wash will flow toward the bottom of the paper.

Apply the wash at the top of the paper, working first from the top left to the right as shown in figure 10-8. Once you have started, don't stop and don't work back into painted areas.

Work your loaded brush back and forth across the paper, keeping the brush loaded with wash. When you reach the bottom, dry your brush and soak up the puddle of wash left there. Your painting should dry smooth and flat. Results will improve with practice.

Painting a Graded Wash

There are two ways of painting a graded wash: from light to dark or from dark to light as shown in figure 10-9. When starting, prepare your drawing board as you did for the flat wash. For a light to dark wash, start with clean water at the top left and add a little darker tone as you progress downward. Further down, add an even darker tone than the first and finish up by removing the puddle at the bottom.

For the dark to light tone, prepare your paper as before. Start at the top left with a dark tone and work downward. Add touches of a lighter tone as you progress downward. Near the bottom you should be using clean water. Pick up the puddle at the bottom as before.

CREATING EFFECTS WITH WASH

Indefinite Blending

Indefinite blending creates many interesting effects and this technique is especially good for creating soft edges for fleecy clouds, furs, or water.

First, float clean water or a wash over the entire area to be painted. Into this wet area, paint one or more dark tones. These will blend into the wet surface and produce an indefinite

Figure 10-9.—Painting a graded wash.

10076

Figure 10-10.—Indefinite blend.

blend as shown in figure 10-10. The tone you add to a wet area should be darker than the final tone desired because the tone is lightened considerably as it blends with the wash or water already on the board.

OPAQUE DRAWINGS

The widely used medium called opaque watercolors can be readily changed because it is of a fast drying quality and is easily controlled.

MATERIALS

For working in black and white, a set of prepared opaque grays, brushes, paper, a large water bowl, and a rag for cleaning the brushes are all that's needed.

The number 3 and number 5 sable brushes you used for transparent wash are used again with the same principle of brush sizes; large brushes for large areas and small brushes for small areas.

Paper with a slight grain or tooth to hold the paint is best for opaque drawings. Illustration board is good because it is heavy enough not to buckle when moist.

When something is opaque, you cannot see through it; nothing of the working surface shows through. When you did wash drawings, you added more water to lighten the tone. In opaque drawings, you add white paint to lighten the tone. You never add water to lighten the tone when working with opaque paints. You do add water, but only to aid the paint in spreading smoothly with the brush.

When preparing to work in opaque paints, the first step is to arrange a series of opaque paints, from white to black, on your palette similar to that shown in figure 10-11. When you need an in-between tone, simply mix two adjacent tones to get the third desired tone.

Opaque greys come prepared, but you may mix your own if you prefer. Simply mix opaque white with varying amounts of opaque lampblack. This mixture will have a slightly bluish cast.

Figure 10-11.—Arranging a series of opaque paints on a palette.

10077 1001

in the 3,000-mc region. Due to the very loose coupling, only about one milliwatt actually reaches the crystal.

A third requirement of a local oscillator is that it must be tunable over a range of several megacycles. This is to compensate for changes in the transmitted frequencies and in its own frequency.

In order to obtain a receiver IF signal of unvarying frequency it becomes necessary to vary the frequency of the local oscillator. The local oscillator must be caused to change its frequency by the same amount that the received signal changes, thereby maintaining a constant IF frequency. The frequency changing of the local oscillator should occur automatically as the received signal frequency changes occur.

In cases where the RF units are located in a remote position, it is desirable to mount the converter section of the receiver remotely also. This insures that the IF frequency (rather than the transmitted frequency) is cabled back to the receiver, but makes it necessary that the local oscillator be tuned from a position some distance away, preferably by varying the voltage applied to it.

The reflex velocity modulated tube (klystron) meets all these requirements very well, and is at present used in most microwave radar receivers. The klystron is also used in Microwave frequency generators or in other applications where a source of low power microwave energy is required. Although the klystron may some day be replaced in many applications by the traveling wave tube, the backward wave oscillator, or the magnetron amplifier, it will probably continue to be an important part of radar receivers for many years to come.

THEORY OF OPERATION

In the circuit diagram of the reflex klystron oscillator (fig. 12-30 (A)), note the arrangement of the electrodes, and the voltages involved in the operation of the oscillator.

Electrons emitted by an indirectly heated cathode are attracted by the cavity grids (buncher grids) G1 and G2, which are positive with respect to the cathode by a voltage E_a. The control grid, situated between the cathode and the cavity grids, controls electron flow. The control grid also has a positive potential (usually about 200 to 300 volts with respect to the cathode. Electrons travel from the cathode toward the cavity grids at a velocity primarily

Figure 12-30.—Reflex klystron oscillator. (A) Schematic diagram; (B) and (C) electrical characteristics

1005

This is unimportant except when the picture is to be reproduced. It is then necessary to add a small amount of yellow ochre or burnt umber to the mixture which will nullify the bluish cast.

WET BRUSH AND DRY BRUSH BLENDING

Wet Brush Blending

Wet brush blending is accomplished by working different values of opaque grays together as shown in figure 10-12. When wet, opaque paint looks different than when dry. Let the paint dry before you rework it if in doubt about a value.

The selection between wet brush and dry brush blending is the illustrator's preference. Both give about the same finished effect.

Figure 10-12.—Wet brush blending.

Figure 10-13.—Dry brush blending.

Dry Brush Blending

Dry brush blending is accomplished by mixing one or two tones halfway between the two tones to be blended. With a dry brush, apply this third tone over the hard edges of the two original tones as shown in figure 10-13.

MIXING MEDIUMS

Although each of the four basic mediums just covered is usually used by itself, many illustrators mix or combine them in a drawing.

Which medium to combine and the amount of combination is determined by the results the illustrator is trying to achieve.

CHAPTER 11

DRAWING THE BASIC FORMS

Form is the basis of all design. All objects consist of form and are three-dimensional in structure, having height, width and depth, and occupying space. We must remember this principle when we portray a three-dimensional object on a two-dimensional sheet of paper. We must create in the viewer's mind the illusion that the drawn object is real and has depth.

All designs, regardless of how complicated they may appear to be, can be reduced to one of or a combination of the four basic forms: the CUBE, the CONE, the SPHERE, and the CYLINDER.

FOUR BASIC FORMS

To draw the forms so that they look real, as in figure 11-1, you will find that by drawing through the object you will obtain the best results; that is, to outline the object both inside and out as if it were transparent. This will enable you to set the object correctly on the paper. Otherwise, you may have the object flat or lopsided or draw two objects which occupy the same space in the drawing. Drawing through the object is illustrated in figure 11-2.

Figure 11-1.—Four basic forms.

Figure 11-2.—Drawing through objects.

In figures 11-3 through 11-6, you can see that every object is not a perfect duplicate of a basic form. The cone in one object may not have a tip, the cylinder may curve or taper, the sphere may resemble an egg more than a round ball, but you can also see the basic form in every one of the designs. Reducing all of the objects to their basic forms has made the objects easier to draw and also aided in laying out the object correctly.

SPHERE

To lay out a sphere, as in figure 11-3a a simple circle is drawn with a line around the center to help construct its depth or thickness. Shading is added to suggest light and the basic sphere is modified slightly until it resembles an egg.

Sometimes the sphere is cut in two as in figure 11-3b to form such objects as cups or domes or, by elongating the circle into an ellipse, a saucer for the cup to sit on.

CUBE

In laying out a shape based on the cube, the main lines are drawn first as in figure 11-4a. Next, the slant on the front of the turret is drawn, along with the placement of the gun, the observation bubbles, and the circular base. Then, by establishing light and shade areas, we emphasize the form.

Following the same procedure as that used to draw the gun turret, the basic form of the landing craft shown in figure 11-4b is drawn first, then refined as design is added along with

10081
08001

light and shadow. As a last step, the details are drawn in to complete the drawing.

CONE

The basic form of the "poplar tree" is a cone as shown in figure 11-5a. By drawing a line down the center of the cone, we locate the main stem of the tree. The use of shade and suggestive modeling further establishes the design. To complete the drawing, we add more detail to the design.

The "Mercury Capsule" shown in figure 11-5b is constructed primarily as a cone with small cylindrical shapes added. When cylinders are seen in perspective, they tend to appear as cones.

CYLINDER

The torpedo shown in figure 11-6a is a cylinder, so the basic cylinder is drawn as the first step in its construction. The tail of the torpedo is constructed from a cone and the nose is constructed as a rounded cylinder. Shadow and light are established and details are added as a final step.

The submarine in figure 11-6b is also a cylinder. By adding design and establishing good light and shadow patterns, the drawing quickly takes on a realistic appearance. Details, as always, are kept for last.

COMBINING THE BASIC FORMS

All of the objects in your surroundings are composed of a combination of the four basic forms. Regardless of how complicated the objects may appear to be, the objects are combinations of the basic forms. You should train yourself to see all objects in their simplest form.

Figure 11-8.—Design formed by combining cylinders and cubes.

Always lay out your drawings using the basic forms and draw through the objects. By doing this, you will be able to correctly lay out any picture you desire to construct. Remember to keep your drawings simple and free of unnecessary lines when laying them out.

The earthmover in figure 11-7 is constructed basically from combinations of cubes with some cylinders such as the tires, and exhaust stack.

The civil war cannon in figure 11-8 is constructed from a combination of cylinder and cubes. The cannon balls are spheres.

The bald eagle shown in figure 11-9, which appears to be very complicated, can be broken down to a combination of cylinders and spheres. The head and body consist of spheres and the legs and neck of cylinders. The feathers are laid out next, but avoiding any detail work until the overall design is complete.

Figure 11-7.—Design formed by combining cubes and cylinders.

Figure 11-9.—Complicated form reduced to basic forms.

Figure 11-10.—Form emphasized by use of light and shade.

FORM REVEALED BY USE OF LIGHT AND SHADE

Light and shade are used to reveal and emphasize the forms of the objects in a picture. As an illustrator, you have the license to arrange the light source to come from the direction which is most beneficial to the effect you desire to create. When there is a light shining upon an object, the object will have a shaded area. Even if the light source is dull, the shaded areas will be there, although they may be harder to distinguish.

When you have a good basic drawing that is correctly constructed, the addition of light and shade will make the drawing more convincing, but no amount of shading will save a poorly constructed drawing. Figure 11-10 shows two well constructed subjects which have been shaded to emphasize their forms.

FORM IN SPACE

You have now learned the four basic forms and how, by reducing your subjects to their basic forms or combinations of the basic forms, you can draw the subjects convincingly on paper. You have seen that with careful placement of light and shade, you can make the subjects even more real and convincing. Now take the basic forms and put them together in a single drawing.

Since each of the forms occupies space and there is space around each of the forms, drawing through each of the objects will help to correctly place them in a drawing so that each occupies only its own space and does not take up the space of any forms near it.

If we were to construct a miniature city block similar to the one in figure 11-11, with its various combinations of forms, we would get a

Figure 11-11.—Layout of forms.

10083

Figure 11-12.—Layout of forms in picture area.

realistic layout of forms, with each form being solid and occupying space, and space filling the area around every form. When the subjects of figure 11-11 are drawn on a sheet of paper, as in figure 11-12, we want to retain that feeling of space and solidness and its three-dimensional appearance. We must remember that space exists in all directions, and many objects, although solid in construction, hold other objects within themselves as shown in figure 11-13.

Each object within or on top of the bookcase takes up a definite space. To draw the entire design correctly, you must allow space for each object, and by drawing through each of the many components of the design, you can accomplish this and make a convincing drawing.

FORM FROM DIFFERENT EYE LEVELS

Different eye levels change the appearance of all objects. If we were to look at a profile of a missile, we would see a cylinder topped with a cone, but if we were to look at the same missile coming toward us, the appearance would be more of two cones end to end as in figure 11-14. You will find that anytime the view of a cylinder is changed to a great degree, it will assume the appearance of a cone. FORMS ALWAYS CHANGE IN APPEARANCE WHEN VIEWED FROM DIFFERENT EYE LEVELS.

We can take our miniature city block and view it from three different angles as in figure 11-15, and see that each of the basic forms appear different in each of the views. You may see a certain object in one view and possibly not at all in another view.

PERSPECTIVE AND FORM

The more distant an object is from the viewer's eyes, the smaller it will appear to be. This

Figure 11-13.—Form within form.

Figure 11-14.—Appearance of form changed by changes of eye level.

10084

Figure 11-15.—Same view seen from three different angles.

Figure 11-16.—Form in perspective.

is the main principle of perspective and everything conforms to this principle. The whole object will appear smaller and smaller as the distance increases and all parts of the object —height, width, thickness and detailed clearness—are reduced proportionately.

As all objects decrease in size in perspective, the area of space around the objects decreases. In figure 11-16, the space between each of the men in uniform is the same, but will appear to be less and less as we look toward the end of the line. The details of the jet in the foreground are easy to see, but of the four jets and aircraft carrier in the distance, we see only enough to recognize the larger shapes.

As the subjects in a picture decrease in size at a distance, they converge toward a definite line in the picture, which is the horizon. The line where the sky and earth meet is the most common of horizons, but, as an illustrator, your eye level makes the true horizon. The true horizon will change everytime you move yourself to a higher or lower position. You are looking at a true horizon when you look straight ahead without moving your head up or down. Another true horizon is where the sky and water meet.

When parallel lines are horizontal, or are level, they appear to converge toward and meet at a definite point on the horizon. This point is called the VANISHING POINT. The vanishing point may be on any point along the horizon. The convergence of horizontal parallel lines is easier to see for large objects, but the same convergence takes place with all level parallel lines regardless of their length.

ONE POINT PERSPECTIVE

For one point perspective, all parallel lines should converge on a single vanishing point as shown in figure 11-17.

Figure 11-17.—One point perspective.

10086

Figure 11-18.—Two point perspective.

TWO-POINT PERSPECTIVE

In two-point perspective, a scene is viewed at an angle, such as from a corner of a building or the corner of a room. From this view point, all parallel lines are seen converging toward two vanishing points on the horizon or eye level as shown in figure 11-18.

Usually, when a two-point drawing is made with a direct view of a corner, both vanishing points will be located outside the picture area.

DRAWING FORM STEP BY STEP

Always select the best possible point of view for your pictures. After you have decided on the view which you feel will make the best picture, establish the correct proportions for the larger objects, and then for the smaller objects. Work only in general shapes. When you are convinced that the view you have selected is best, and you have a very rough outline with the larger objects drawn proportionately correct, you should re-

Figure 11-19.—Drawing form step by step.

determined by the magnitude of the voltage E_a. Most of the electrons pass through the control grid and the cavity grids, and continue on toward the repeller plate.

After passing the cavity grids, the electrons approach a region where the electrical field opposes their motion (since the repeller plate is negative with respect to the cathode by the voltage E_R). This voltage is variable and is usually about -100 volts, making the magnitude of the voltage from the repeller plate to the cavity grids about 300 to 400 volts. This potential slows down the electrons, causing them to come to a stop, after which they reverse direction and pass back through the grids toward the cathode.

Most of these returning electrons are collected by the cavity grid nearest the cathode, by the accelerating (control) grid, or by the metal shell (envelope) of the tube. Those electrons that are not collected continue on toward the cathode until they are again reversed in direction by the action of the accellerating field, and are sent back through the cavity a third time. These electrons that have not been collected cause improper tube operation—an undesirable feature which is partially eliminated through tube design.

In most circuits involving resonant cavities, oscillations start from some irregularity in current flow—such as a transient condition resulting from the sudden application of voltage to the tube elements, or from the "shot effect" of cathode emission. Keeping this in mind, assume that oscillation in the resonant cavity is already taking place.

With the tank circuit oscillating, a high frequency voltage (e) appears between the two cavity grids, causing the electric field to reverse twice during each cycle. As the electrons approach the grids, the electron stream is nearly of uniform density and velocity. The time required for the electrons to pass through the space between the grids is small compared to the period of the oscillation.

Electrons entering the space when e is zero encounter no a-c electric field, and pass through with no change in velocity. Electrons entering the space when grid G2 is positive with respect to G1 encounter a field which tends to accelerate them. (The amount of acceleration is a function of the magnitude of e.) Electrons entering the space when e is of the opposite polarity are decelerated.

The change in velocity due to acceleration and deceleration is small in comparison with the original velocity. The electrons which are accelerated most travel farther toward the repeller plate before being turned back, while those that are decelerated most are turned back sooner. With proper magnitudes of e, E_a and E_R, electrons returning to the cavity grids may be made to arrive in "bunches."

Figure 12-30 (B) shows the relative position of electrons in the tube at various times during their transit. The zero distance position, taken as the baseline of the graph, is midway between the cavity grids.

Electron a, which arrives when G2 is positive, is accelerated and travels farthest before being turned back; electron b is unaffected; electron c is decelerated and turns back after a short excursion. Hence, in the diagram these electrons (and the ones passing through at intermediate times) are shown as arriving back at the grids at the same time.

This is the ideal situation, but in actual operation electrons return to the grids in a stream that varies in intensity at the frequency of the oscillations. The tube is called a REFLEX velocity-modulated tube, because the electrons reverse direction and travel through the interelectrode space twice.

On the return trip the electric fields set up by the voltage e again act upon the electrons. Since they are now traveling in the opposite direction, they will be decelerated if they return when G2 is positive and accelerated if they return when G2 is negative. When an electron is accelerated by an electric field, its kinetic energy increases; this additional energy is taken from the electric field. On the other hand, an electron which is decelerated gives up energy to the electric field.

If the bunches of electrons can be made to return when G2 is positive, they will give up energy to the alternating field. For maximum transfer of energy the returning bunches must arrive when G2 is maximum positive. The question arises as to where this energy originates. Remember that if the electron stream from the cathode is uniform, some electrons are accelerated and some are decelerated on the outbound trip by the electric field of e. On the average, as many electrons absorb energy from the field as give up energy to it.

duce all of the objects to their basic forms. Remember to draw through the forms to establish a convincing likeness of the object and their existence in space, and also to place them in space correctly.

You should then add the light and shadow patterns to emphasize the forms and strengthen the appearance of the three-dimensional forms. When you have reached this point, you are ready to add detail. You should overcome the tendency to add details immediately, and save them for the last step, as shown in figure 11-19.

ARRANGING FORMS IN SPACE

The arrangement of forms in space, the use of perspective, and space itself contribute greatly to the impact of the picture. Although many objects and details are to go into a picture, primary establishment of these forms and their setting must take place before attention is turned to the details. Figure 11-20 illustrates the steps which should be followed for a well-constructed picture.

EVERYWHERE - THE VARIETY OF FORM

Every object is different, in some respect, from every other object. This difference in objects, even those of like construction, is what makes the object interesting. The difference also enables us to separate things and identify them.

As an illustrator, it is your job to train yourself to observe these differences so that you can use them in a picture. You should form an interest in the great variety of forms in order to recognize those differences which make every form unique. Figure 11-21 shows the profile of three human heads, and although they are constructed around the same basic structure, the skull, each has its own personal identity which is different from every other head in the human race.

TEXTURE BY REPEATED FORMS

Whenever a form is repeated often enough, a new texture will result. The new texture is not achieved simply by multiplying the original form, because in nature, no two objects are exactly the same, but the repetition of the original shape in varying size will blend to form an overall tone and texture design. Figure 11-22 shows three distinct forms, the leaves on the tree, the bricks of the fence and the grass, which are repeated to form a pattern.

Figure 11-20.—Arranging form in space.

Figure 11-21.—Difference in form of the human head.

Figure 11-22.—Texture by repeated form.

10089

Figure 11-23.—Variety of textures.

VARIETY OF TEXTURES

We can readily recognize an object not only by its form, but also by the texture of its surface. An object can be smooth or rough, soft or hard.

In your pictures, you must capture the illusion of surface textures for objects. To do this, you should know the identifying characteristics of the object thoroughly.

It is sometimes helpful to think of how the object feels to the touch, then decide how it could best be rendered. Figure 11-23 shows a number of objects which illustrate this principle.

TEXTURES AND DETAILS AFFECTED BY DISTANCE

Distance, as we said when dealing with perspective, has a great influence on textures and details. When we see an object close up, we can see the texture of the object and the details of its construction quite easily, but, as we introduce distance between the object and our eyes, we will see less of the objects texture and fewer of its details.

If you take a quick look around at your surroundings, you can easily see all the details and texture of the objects which are close to you. But, look across the room. How well can you see details of those more distant objects? When you are constructing a drawing, you want to capture this sense of depth in order to give realism to the drawing. By following the principle that less texture and fewer details are seen as distance is increased between you and the object, you will be able to create realistic drawings.

The fact that you know the texture of a distant object does not mean you can really see the texture, and when you are drawing realistically, you draw the object as it is seen in reality. Objects in the background should be less well defined than those in the foreground. Figure 11-24 shows the same subject at three different distances from the viewer. You can easily see the application of this principle in the illustration.

Figure 11-24.—Textures and details reduced by distance.

CHAPTER 12

DRAWING HUMAN FIGURES

In some of your work you may be called upon to draw human figures. This is one of the most difficult skills to be acquired in the field of illustrating, and this chapter can only cover some of the general principles to follow and some basic techniques to use in drawing human figures.

The principal reason most beginners have trouble drawing the human form is that they want to immediately start drawing a fully clothed subject in a complicated pose. The beginner may also spend a great deal of time concentrating on details of features, anatomy, and drapery at the expense of the whole. In his concern for details, he loses his sense of proportion and construction, and, most important of all, the figure's form loses its solid appearance.

There is only one sound approach to drawing the human figure: begin by having a very clear concept of the figure's basic form. The human figure is the same as the basic forms explained in chapter 11 in that it is a three dimensional object—a solid object with bulk and weight.

The human figure appears to be a highly complex form. It is obviously not a single sphere, cube, or cylinder. But when you examine this complex figure closely, you can see that it may be drawn as a combination of simple forms—forms closely related to the basic spheres, cubes, and cylinders you learned to construct in chapter 11. If you can draw the basic forms, you should have no difficulty in putting them together to make the total human form.

In this chapter you will be shown how to analyze the human figure in terms of the single basic forms. You will learn about the proportions of the component forms in relation to the total form, and about the ways these component forms are joined and how they move. You will be shown how to draw the basic human forms in various positions both at rest and in motion. You will also see how the form changes as a person grows from a child to an adult.

Be sure to master the figure's basic form before attempting detailed illustrations. Practice drawing the basic form in as many positions and attitudes as possible. Use photographs, paintings, and the people around you as models. If you wish to become more proficient in figure drawing, you should then study one of the commercially published books on the subject—one which covers artistic anatomy and the special problems encountered in drawing the individual parts of the body.

THE HUMAN FIGURE—A SOLID FORM

The human figure is a solid form; it has depth as well as height and width; it exists in three dimensions. Whether the artist forms the figure out of clay or stone or draws it on paper, he must think of it as a three dimensional object. Since the flat surface of the paper lacks the third dimension of depth, the artist must create the impression of depth. This is best accomplished by drawing through the solid form—the same procedure you learned in chapter 11.

BASIC FIGURE FORM

Figure 12-1 shows the simple basic forms which make up the total form of the human figure. Only the important forms are shown; all distracting detail is eliminated. The important forms are the head and neck, the upper and lower torso, the upper and lower arms, the upper and lower legs, and the hands

10091

Figure 12-1.

and feet. You can see in both the model and the form drawing that the neck, arms, legs, and torso are essentially modified cylinders, the head is basically a sphere, the hands are cube forms, and the feet are a combination of cones and cubes.

FIGURE PROPORTIONS

The human head is used as the BASIC UNIT OF MEASUREMENT for proportioning the entire human body. The vertical height of the head from the chin to the top of the skull is used for all vertical measurements, while the width of the head is used for making all horizontal measurements. For example, the shoulders of the illustrated body are approximately three head widths across.

The average human figure is 6 1/2 heads high, but the ideal height of the illustrated figure is eight head units high. After the height of the figure has been decided, it should be divided into eight equal parts. After drawing the head, you should draw the other parts of the body along the vertical axis. The illustrated figure is slightly taller and slimmer than a person of average height and build.

As shown in figure 12-2, the eight head units of height are divided as follows: the head itself is "one head unit"; about 1/3 of a head unit is allowed for the neck; and 2 2/3 head units are allowed for the torso (from the bottom of the neck down to the crotch). This totals half of the figure's height. Of the four head units remaining, two units are used to measure the upper leg to the area just below the knee, and the remaining two head units indicate the height measure from below the knee down to the soles of the feet. Although the male figure is usually taller than the female and has a different outline, the same eight head units of measurement should be used for both male and female proportions. The head unit cannot be stated in a specific number of inches; each figure must be measured in terms of its own head size.

For correct proportions, you must rely on your visual perception. The use of the head as a unit of measurement is convenient and helpful while you are first learning figure proportions, but only when the figure is standing upright can you actually measure the body in terms of head units. Most of the time, you will find that the figure or parts of it are foreshortened as shown in figure 12-3. Only with your own eyes can you determine the

Figure 12-2.

10092

Figure 12-3.

foreshortening necessary for the construction of a correctly proportioned figure for a drawing.

When an object is slanted toward or away from you, it is foreshortened. This is an application of the principle of perspective in which the object seems to diminish in size and change in shape as it goes back. If the object were a cylinder, the sides would appear shorter and the ellipses nearer to being circles as the foreshortening increases. If the object were a cone, the point would appear to rest closer to the center within the shape and the ellipses would again approach a circular shape as the foreshortening increased.

The only way to gage proportion is with your eyes. If it looks right, it is right. Skillful drawing is skillful seeing which the artist transfers to his drawing paper.

Figure 12-4.

10093
10093

Structural Differences in the Male and Female

Figure 12-4 shows the differences between the average male and female illustrated forms. You can see that the male's shoulders are a full three heads wide, but his hips are much narrower than his shoulders. The female's shoulders are narrower than those of the males, but the female's hips are about the same width as her shoulders. Also, the female's shoulders are more tapered than the male's, and her arms, wrists, and fingers are smaller and thinner than the male's. The female's lower legs taper to thinner ankles and smaller feet than do the male's.

Changing Proportions at Various Ages

At birth, a baby's head is quite large compared to the rest of his body. At the age of about one year, the body from neck to feet is about three and one-half times the length of the head. The overall height is four and one-half heads as shown in figure 12-5a. The center of the body at one year is at a line drawn across the the stomach.

At the age of eight years, the center of the body has moved down to a line above the hips as shown in figure 12-5b. The arms and legs have become longer and the head is somewhat larger. The overall height of the body is approximately 6 and 1/4 heads.

At the age of twelve, the overall figure is seven heads high, and, as shown in figure 12-5c, the center line is now at the crotch, which is the dividing point of the average human body. From this age on, the body broadens out, becomes taller, and assumes

A. ONE YEAR B. EIGHT YEARS C. TWELVE YEARS

Figure 12-5.

10094

the characteristics of the typical male or female form.

CONSTRUCTING THE FIGURE

For the purpose of constructing a drawing, the human figure may be divided into five components: torso, arm, leg, hand and foot, and head. Each of these components, in turn, may be considered to consist of the basic forms explained in chapter 11.

THE TORSO

The easiest way to visualize the human torso is to reduce it to two cylinders. The upper cylinder is twice the height of the lower cylinder as shown in figure 12-6.

Figure 12-6.

Figure 12-7.

Figure 12-8.

THE ARM

The upper and lower arms are modified cylinders of approximately equal lengths as shown in figure 12-7. The cylinders for the arms are very much like the cylinders used for the construction of the torso, only much narrower. The cylinders forming the arms may be drawn at a much greater angle than the cylinders forming the torso because the arm bends much more than the torso.

THE LEG

The upper and lower legs are also modified cylinder forms of approximately equal length as shown in figure 12-8. The two sections of the leg are joined at the knee and are designed to bend in the opposite direction to the arm.

THE HAND AND FOOT

The hand and the foot are not as easily reduced to basic forms as are the three parts of the body described previously. They can, however, be shown as a combination of simple forms which represent them with reasonable accuracy. Figure 12-9 shows how a combination of a cube and a wedge shape will represent the hand. The cubic form symbolizes the palm of the hand while the tapering wedge represents the mass of fingers. The finger wedge is about the same size as the cubic area of the palm. The hand can also be represented by joined planes.

The upper portion of the foot may be reduced to a cone with the point cut off. This cone is not symmetrical in shape; the back rises almost straight up while the front is rather slanted as depicted in figure 12-10. The form of the toes and the entire sole are best shown as a very thin cubic form.

These basic approaches are enough for you to learn as a beginning. Later, you will learn more about the form, structure and anatomy of the hands and feet of the human figure.

THE HEAD

The basic form of the head is a modified sphere, very much like the shape of an egg.

Figure 12-9.

Figure 12-10.

10096
1991

Figure 12-11.

The head rests securely on the neck, which is a short cylinder. The nose and ear are not part of the basic form; they actually project from the surface of the head's form.

The head seen from a side view is slightly different than when seen from the front view. From a side view, it can be seen tilted with the neck toward the rear of the head and slanted forward as shown in figure 12-11. The eyes should be located on the horizontal center line, with the eyebrows slightly above the line of the eyes. The nose extends from the eye line, halfway down to the chin. The top of the ears line up with the brows and the bottom of the ears line up with the bottom of the nose. When seen from the side, the ear rests just back of the center line of the head. The jaw line curves down from the front of the ear.

MOVEMENT OF BODY PARTS

The individual parts of the body are connected by three distinctly different types of joints which make a variety of body movements possible: the ball and socket joint at the shoulders and hips; the hinge joint at the knee and elbow; and the flexible column of the spine and neck. Each of these joints varies considerably in the type of motion it allows, and the amount of motion depends on the construction of the individual joint.

BALL AND SOCKET JOINT

The ball and socket joint shown in figure 12-12 is extremely flexible. Those parts of the body constructed with this type of joint can be rotated in practically any direction. Although not ball and socket joints, the wrist and ankle joints permit similar rotary movement.

HINGE JOINT

The hinge joint in figure 12-13 works very much like the ordinary door hinge. It allows the forearm to swing forward and the lower leg to bend backward and to straighten out again. It does not, however, permit the forearm or the lower leg to bend sideways.

FLEXIBLE COLUMN

The flexible column (spine) shown in figure 12-14 connects the upper and lower halves of the body. The upper most portion of the spine

10097

Hence, very little net energy is taken from the oscillating circuit during the bunching process.

The average kinetic energy of the electron is that imparted to it by the d-c voltage E_a. Thus some of the energy taken from the d-c electric field is transferred to the a-c field to sustain the oscillations. The power output is taken from the klystron with an inductance loop located inside the resonant cavity.

Modes of Operation

It is not necessary that the bunches of electrons return to the grids on the first positive swing of G2. Figure 12-30 (B) indicates that if the bunches arrive on the second positive swing, the net result is still the same. The time in transit for the average electron (b) is 3/4 cycle, 1 3/4 cycles, 2 3/4 cycles, and so forth. In actual practice there are three or four "modes" in which oscillation is possible. The darker lines in the illustration indicate paths of electrons operating in the first mode, while the lighter lines indicate paths of electrons operating in the second mode. The third mode is possible when the average transit time is 2 3/4 cycles.

The following explanation shows how transit time is controlled to produce the oscillations in different modes. Since the original velocity of an electron depends on the d-c voltage E_a, and since the distance that the electron travels before turning back and the speed with which it returns depend upon the difference between E_a and E_R, it is possible to adjust the two voltages E_a and E_R for any of the modes.

The voltage E_a is usually fixed in magnitude. Varying it would change the initial velocity, which would in turn vary the excursion and the return velocity. E_R is made variable, since it is not feasible to vary E_a. For operation in the first mode, the round trip must be completed in the shortest time. This is accomplished by making the repeller plate highly negative. For longer time in the interelectrode space, the repeller plate is made less negative.

Figure 12-30 (C) shows power output and frequency as functions of the repeller voltage for three modes of operation. Notice that the frequency at the point of maximum output is the same for all three modes, and is the resonant frequency of the cavity. Note also that the power outputs of the various modes at the resonant frequency are not the same, and that the output is least in the highest mode. This may be explained by examining the factors which limit the amplitude of the oscillations, and which in turn limit the power output.

Power and amplitude limitations are due to "overbunching" as well as to the usual losses in the oscillatory circuit. Overbunching occurs in the following way: As oscillations build up and e becomes greater, the amount of acceleration and deceleration increases. This causes bunching to occur within a shorter period of time; that is, before the electrons reach the grids on the return trip. This tends to reduce the magnitude of oscillations. In the higher modes of oscillations where the bunches are formed more slowly, the electrons are more susceptible to overbunching. The magnitude of e which results in overbunching is therefore lower and oscillations are limited by this action to a lower amplitude than in the lower modes of operation.

As shown in figure 12-30 (B), the frequency of oscillations in a reflex klystron is variable to a limited degree in any of the modes of operation by means of varying the repeller voltage. When the repeller voltage is varied, it causes a bunch to return a little sooner or a little later than normal. Off resonance, the amplitude of oscillations decreases by an amount which depends on the Q of the cavity. The tuning range is small in comparison to the frequency of oscillations and varies somewhat from one mode to another, being greatest in the highest mode. This can be explained from the fact that in the highest mode, bunching and debunching take place at a slower rate and that greater variation from the ideal time of return is possible without debunching, causing the amplitude of oscillations to drop below this usable output level. Another way to look at it is that in the highest mode the interval between leaving the grids and returning is greater, and the change in period represented by a given change in frequency is a smaller portion of the interval.

Operation Characteristics

The band of frequencies which can be obtained by varying the repeller voltage lies between the half-power points shown in figure 12-30 (C). This range of frequencies is known as the ELECTRICAL BANDWIDTH. The output curves of the bandwidth are unsymmetrical about the maximum output points. This results from

1007

Figure 12-12.

is the neck which connects the head to the upper part of the body and controls all movement of the head. The spine is involved in all actions which require shifts in weight such as walking, running, or jumping. The spine is highly flexible and not only allows turning motions in all directions, but also permits a twisting motion throughout its entire length.

BONES AND MUSCLES IN FIGURE DRAWING

Bones and muscles have a distinct bearing on the outward appearance of the body and on the actions that the body can perform. After starting with the basic figure, you can use the bone and muscle structure to refine the simple basic forms and make them more life-like. In doing so, remember that the bones and muscles are not flat

Figure 12-13.

bands or lines beneath the skin; they are solid forms that protrude from the surface of the figure or cut back into it.

Do not think that putting more bone and muscle into a drawing will make it appear more realistic. You will endup with a medical chart instead of a figure drawing. Time and effort can be well spent in studying and drawing the forms and actions of the bones and muscles as they affect the outward appearance of the figure.

Figure 12-15.

BONE AND MUSCLE IN THE MALE AND FEMALE

Figure 12-15 shows the major differences of the bone and muscle structure of the male and female figures. While the female has the same bones and the same muscles as the male figure, the female's bones are smaller and smoother, and her body is heavily covered with fatty tissue, especially thick over the thighs, hips, and buttocks. Female muscles are almost always less developed than male muscles. The heavy covering of fatty tissue over the female's body causes the bones to be less apparent on the surface.

The breastbone or "sternum" in the male is longer and less curved than in the female. The male's hip section or "pelvis" is narrower and deeper, about the same width as his rib cage, while the female's pelvis is proportionally wider than her rib cage, giving her much wider hips. In the male, the distance from the pelvis to the rib cage is shorter, causing the length of the male torso to be proportionally shorter than the female torso. In the male figure, the legs are proportionally longer than the female's legs.

Having a shorter, straighter collar bone causes the female to have narrow, sloping shoulders and a longer neck than the male figure. In proportion to the trunk (torso), the male's arms are longer than the female's. Because of the longer "humerus", or upper arm bone, the male's elbows are lower than the female's elbows. The male skull is usually larger than the female skull.

CONSTRUCTING THE HEAD

When constructing the head, some important points to remember are (1) the nose is an

Figure 12-16.

Figure 12-17.

eye length wide, (2) the front of the head at the brow is 5 eye lengths across, (3) the lower lid is recessed beneath the upper lid, (4) the lower eyelid is less arched than the upper, and the upper eyelid lies on a wider curve of the eye ball, (5) the base of the nose, base of the cheek bone, base of the ear lobe, and base of the skull ALWAYS lie on a line drawn across the head, and (6) to correctly place the eye in its socket, start the corner of the eye on a line drawn directly above the end of the nostril. These points are shown in figure 12-16.

The features of the facial area change in appearance or the viewing angle is changed. In the three quarter front view shown in figure 12-17, the basic shape of the head is sketched first with horizontal and vertical guide lines locating the eyes. In this view, the horizontal line curves around the head. The far eye will not be as large as the near one since it is further away. The features are located next. In this view, the far eye will be slightly covered by the projection of the nose. The side planes of the head and nose are now established and the depression of the eye socket is indicated. The far side of the mouth will be smaller as it curves around the face.

In drawing the three quarter back view, the first step is to sketch the basic shape of the

Figure 12-18.

head. In this view, only small portions of the facial features are seen, and they are located by guide lines as before. The features are developed with careful attention being paid to the ear, since it is now the most pronounced feature visible. Very little of any forward features are seen, but that which is seen should be drawn as carefully and accurately as possible as shown in figure 12-18.

The horizontal and vertical guide lines used in constructing the head change their shape when the head is drawn in tilted or leaning positions. Notice that the guide lines in figure 12-19 become curves or ellipses as they turn around the solid form of the head. When drawing the head in different attitudes, you should remember to draw through the head in order to retain the correct relationship of features and the solid, roundness of the head. The neck should be drawn as a cylinder, without details, which fits onto the upper torso. Notice that the neck is lower in front than it is in the back. Figure 12-19 shows how the head looks as it is turned or tilted in various positions. You should practice drawing the head in these different positions until you can do each one well. Remember to start with the basic form; draw through all lines; and retain the solid three-dimensional appearance of the head.

Facial Details

THE EYE.—The eyeball, about the size of a golf ball, is the most expressive feature of the face, but it is also the most delicate. Because of this, nature has designed extensive protection for it—the eye socket. The eyeball is protected by structures of bone: the brow ridge (frontal bone of the forehead) on top, and the cheek bone on the bottom. The nose offers protection on the inner side.

The eye has two lids which curve like short visors on the eye. The upper lid curves wider across the circumference of the eyeball while the lower lid turns on a shorter arc around the base of the eyeball. Both lids have lashes. The inner and outer corners of the eyelids are completely different in design. At the outer corner, the upper lid overhangs the lower lid. At the inner corner the lids do not touch when the eye is open, but are separated by a narrow area of pinkish membrane. (See figure 12-20).

THE NOSE.—The nose, the long wedge-shaped form projecting from the center of the facial area, is thin and narrow at the top and thick and wide at the bottom. The upper half has a bony structure while the lower half consists of cartilage (an elastic tissue) which is flexible and responds to the actions of the facial muscles. The lower part of the nose consists of five pieces of cartilage as shown in figure 12-21. Two pieces form the tip, one piece each to form the nostrils, and one piece forms the hook of the nose to separate the nostrils. The hook of the nose descends lower than the nostrils.

The nostril cavities are triangular in shape and vary according to individual size of the

10103

Figure 12-21.

Figure 12-22.

001010104

Figure 12-23.

nose; they are slanted outward toward the back of the nose.

THE LIPS, MOUTH AND CHIN.—The mouth is the most flexible of all facial features. The upper lip is shaped like a flattened "M" and has three sections; the lower lip is shaped like an extended "W" and has two sections. The center section of the "M" thrusts forward like the prow of a ship and rests in the center groove of the lower lip when the mouth is closed. The two sections of the "W" take the form of two elliptical lobes.

The lower lip is recessed beneath the upper lip and, when seen in profile, the lips are located on a line sloping backward from near the tip of the nose to the furrow at the top of the chin. This can be seen in figure 12-22.

There are slight depressions or hollows where the corners of the mouth meet the lower cheek. This is usually more pronounced in the male face.

When the mouth is seen in a smile or laugh, the corners of the mouth are pulled back and the upper lip appears to be straighter as the lower lip becomes more curved. When the mouth is in an open, smiling position, the upper teeth are visible. Rarely are the lower teeth seen except in extreme actions of the mouth.

The chin bulges forward at its center. From the front, the chin usually appears to be nearly straight across with a depression in the center. The shape of the chin usually matches the character of the rest of the facial features.

THE EAR.—The ear is a mass of cartilage and soft flesh. It is wider at the top rim and narrower at the bottom (lobe). In the middle of the ear is a bowl shape which is surrounded by whorls and curves of flesh-covered cartilage. The ear has four major shapes: (1) the outer wider rim, (2) the inner rim, shaped like a bent "Y", (3) the bowl area, and (4) the fleshy lobe.

Correct positioning of the ear is the most important phase of drawing the ear. Emphasis may then be given to the hard forms of cartilage and the soft flesh of the lobe. We have already mentioned that the top of the ear is on a line with the eyebrow and the bottom on a line with the base of the nose.

When seen in profile, the ear is located halfway between the front and the back of the

Figure 12-24.

0010105

head location. When seen from the front, the ear slants downward and parallel to the side planes of the head as seen in figure 12-23.

WALKING AND RUNNING

When a person walks, the body shifts its weight alternately from one leg to the other, and the center of gravity passes through the foot on the ground. When the figure is running, the body leans in the direction of movement, ahead of the center of gravity. The faster the speed, the more the body leans. The figure in both walking and running attitudes is shown in figure 12-24.

CLOTHING THE FIGURE

The folds formed on a clothed figure are controlled by three factors: the shape of the figure, the action of the figure, and the cut of the garment. The folds formed primarily by the law of gravity are supported by the shoulders for the shirt, blouse and coat and by the waist for the trousers or skirt. These folds are usually long and flowing. The main points for folds formed by tension are at the shoulder-arm junction, the elbow, the waist, the leg-torso junction, and the knee. When the arm, torso, or leg is bent or changes direction, the cloth slackens on the opposite side of the tension. The cloth on a figure does not change in amount, but it is condensed. As it is condensed, it creates folds in different shapes and in different places. The shape, place, and direction that the fold takes is determined by gravity, tension, support, and action.

Figures 12-25 through 12-27 show examples of folds in male clothing; figures 12-28 through 12-31 show examples of folds in female clothing.

Figure 12-25.

10106

the fact that if E_R is increased, not only does the bunching voltage e decrease and cause bunches to form at a later time, but the repeller voltage causes a quicker return and the effects of the two actions add to cause poor bunching at the time the electrons return, resulting in a rapid drop in output on the high side of the hump. At lower voltages (even though the bunching voltage e decreases and causes slower bunching) the decreased repeller voltage causes a later return to the grids. The two effects are counteracting and a greater change in repeller voltage is possible before the output drops below the usable level.

The choice of the point and mode of operation is a compromise among several factors. There are several modes which have the necessary power output. It would seem that the correct choice would be the highest mode, for it gives the largest tuning range. The highest mode, however, is too sensitive to a change in voltage to be well regulated. A change of 1 volt may cause a change of 0.5 mc in the 3,000-mc oscillator. Since the humps are unsymmetrical, the point of operation is usually chosen a little below the frequency of maximum output. This makes it possible to tune above the operating frequency by a greater amount than if the maximum point were used.

REFLEX KLYSTRON

In a radar set, the reflex klystron is usually used in conjunction with an automatic-frequency-control circuit; a circuit which frequently is used to control the repeller voltage to maintain the correct intermediate frequency. Keep in mind that the frequency of oscillation is primarily determined by the dimensions of the cavity, and that the repeller voltage is effective in making small changes in frequency. Hence, in most reflex klystrons there is a coarse frequency adjustment which varies the cavity size, and the repeller voltage is the fine frequency adjustment. The dimensions of the cavity are changed (fig. 12-31 (A)) by a mechanical adjustment.

It is true that the klystron frequency is primarily determined by the size of the cavity. However, once built, the spacing between grids G1 and G2 (fig. 12-30 (A)) is the controlling factor, and a mechanical adjustment is provided which physically controls their spacing. Moving the grids closer together increases the capacity between them and consequently reduces the output frequency. Although this adjustment may also reduce the overall size of the resonant cavity, that effect is small as compared to the effect of the change of capacitance.

KLYSTRON THERMAL TUNING

It has been found advisable in the later types of equipment to operate the klystron local oscillator at a point of maximum output (klystron tuned for maximum crystal current). This is necessary because the noise output of the local oscillator is at a minimum at this point. Maximum output is obtained when the klystron cavity is resonant to the output frequency. In order to accomplish this in a practical installation, it is necessary to use a tuning mechanism that permits remote control of the cavity dimensions of the klystron.

One method of accomplishing this is through the use of a remotely controlled cavity tuning motor. In another method of remotely tuning the klystron cavity, the tuning mechanism is a part of the klystron. In one tube of this type the upper section contains a triode. (See fig. 12-31 (B).) The plate of the triode changes in length in accordance with the temperature of the plate, which in turn varies with plate current.

The variations of the triode plate length are impressed through mechanical linkage on the cavity of the klystron. Thus, by controlling the grid voltage of the trode (and its plate current), it is possible to vary the dimensions of the cavity in the klystron. This is known as THERMAL TUNING.

In some tubes the triode is replaced by a diode. This diode has a control tube connected in series with it and a B supply. By varying the bias on the control tube it is possible to control the diode plate current, which varies the dimensions of the klystron cavity.

INPUT CIRCUITS OF UHF RECEIVERS

Much of the material that follows in this chapter is reprinted by permission from Principles of Radar, Third Edition, by Members of the Staff of the Radar School, Massachusetts Institute of Technology, Copyright 1952, McGraw-Hill Book Company, Inc.

Proper selection of the input circuits to UHF and microwave receivers is a design consideration. Proper functioning of these circuits is an important operating and maintenance

Chapter 13

COMPOSITION AND DESIGN

The composition of a piece of art refers to the way in which its various elements are selected, combined, and arranged within the picture space to express the illustrator's ideas clearly and effectively to the viewer.

In a sense, composition means combining forms and space to produce a harmonious whole. When composing a picture the primary interests are; (1) where to place the objects in the picture space, (2) how important in size and value the objects are to be made, and (3) the relationship of the objects to each other.

Objects in a drawing can be made large or small, depending on the importance you want them to have. Important objects should be made larger or clearer than less important objects which are made smaller and less distinct.

Since in any two layouts the components are never the same, you cannot use a set of ready-made formulas to compose a layout. You must depend on what looks best to you, designing each job individually according to what is to be communicated.

First, analyze the components that are to go into the layout. Then determine which component is the most important so that it may be given the greatest emphasis. Try to picture in your mind the components as they will appear when the layout is completed. This takes practice, but you should learn to think in terms of the finished product from the first.

BASIC THINKING AND ARRANGING

You may find it difficult at first to visualize the complete layout. One helpful method to overcome this difficulty is to visualize each component separately. Draw each object to size and shade it to approximately the tones desired. Now you can cut out each of the separate objects and, on another sheet of paper upon which you have penciled the borders of your layout, place the separate objects in the position that you feel is best. When you view these objects in place, some may appear too large or too small or not in harmony with the other components. Redraw the inharmonious objects and move the objects about until you find an arrangement that appears right to you; one that you feel will make a good layout. This procedure is shown in figure 13-1.

Another method of composition selection used by illustrators is drawing thumbnail sketches, as shown in figure 13-2 and selecting the best one to work into a finished layout. The small size of the thumbnail sketches makes it easier to see the pattern as a whole. However, you may find that a thumbnail sketch that looks good when it is small will lose its harmony when you enlarge it.

EIGHT MAIN ELEMENTS IN PICTURE COMPOSITION

There are eight main elements in composition; (1) the picture area, (2) the picture depth, (3) the line movement, (4) the value, (5) the proportion, (6) the balance, (7) the unity, and (8) the clarity. The last four elements pertain more to poster design than to situation type illustrations.

PICTURE AREA

The picture area is the area within the borders, as seen in figure 13-3. The size of the objects drawn should be influenced by the overall size and shape of the picture area. To use the picture area most effectively, you should study the objects and their size before locating them in the picture area.

10112

Figure 13-1.—Moveable object.

Figure 13-2.—Thumbnail sketch.

Variation of Subject Size

One of the most effective ways of judging the importance of an object in your picture is by noting the relative size of the object. You may give any object importance by drawing the object in the foreground and making the other objects in the picture smaller. This is shown in figure 13-4. The size of the objects and their location determines their relative importance in a picture. You should never choose an object's size without first considering its effect on the layout.

Overlapping Objects

Most pictures you draw will probably have more than one object in them and each of these objects will probably differ in size and shape from the other objects. You may obtain better organization of varied objects and a more interesting and unified arrangement by overlapping. Look around, almost everything you see is partly hidden (overlapped) by other objects. Overlapping may also be used to help emphasize the main object (s) by partially obscuring secondary objects. (See fig. 13-5.)

Figure 13-3.—Picture area.

A. FIGURE IN FOREGROUND COMPLETELY OVERWHELMS DISTANT FIGURE.

B. THOUGH NOT SO GREAT A DISTANCE BETWEEN FIGURES, FIGURE IN FOREGROUND STILL DOMINATES PICTURE AREA.

C. HERE NEITHER FIGURE IS DOMINANT BECAUSE OF DISTANCE, BUT FIGURES THE SAME SIZE SHOULD BE USED ONLY IF SITUATION PERMITS, OTHERWISE, THIS ARRANGEMENT COULD BECOME MONOTONOUS.

Figure 13-4.—Variations of subject size.

10114

Figure 13-5.—Overlapping objects.

Figure 13-6.—Cropping.

10115

Cropping

You may also use the border of the picture area to overlap objects; cropping (using only a portion of an object). (See fig. 13-6.) However, the visible portion of the object must be typical enough to identify the object.

PICTURE DEPTH

Depth in a drawing is created by giving the viewer the impression of distance or three-dimensions. The suggestion of depth in a picture makes the scene appear more realistic. Overlapping aids in creating the illusion of depth. Another way to create the impression of depth is to draw some objects smaller than others to suggest that they are further away from the viewer. Purpose and effect should be the main guiding factors when you are creating the illusion of depth in a picture.

Always examine your depth effects carefully to decide whether you have placed the objects at the best depth to achieve the desired effect. If not, make any changes or adjustments which you feel will help to achieve the desired effect.

Creating Interest by Use of Depth

Using overlapping, cropping, and different sized objects to create a sense of depth is not enough to create a good composition. All of these methods should complement each other to form an interesting composition. Unless there is some special reason for doing so, never place objects in a line or row, crowd them into half or a quarter of the picture area, or regularly arrange different illustrations in the same design. To create interesting and appealing compositions, you should place the objects in varied and interesting patterns.

Interest is often increased by selecting a view other than the one you originally started with. Don't be satisfied with ordinary composition. Guard against the tendency to repeat the same basic arrangements in all of your pictures; try to create something original with each assignment. Think and experiment; move the objects around until you arrive at new, different, and interesting effects.

Creating Depth by Use of Props

Props, objects of known shape, can aid in creating a sense of depth in your pictures if you arrange them to lead the viewer's eye back into the center of interest. (See fig. 13-7.)

LINE MOVEMENT

The term line is used here to mean the direction in which the viewer's eye moves as he looks at a picture. This directional line is created by arranging the objects so that the shapes of the main lines will lead the viewer's eye to the center of interest. Your pictures should be designed to lead the viewer to the center of interest. Directional lines may move

CREATING DEPTH BY USING THE RECEDING TABLE AND OVERHEAD LINE. THE LINE OF THE RIFLE AND BAYONET LEAD TO CENTER FIGURE.

Figure 13-7.—Picture depth, depth by use of props.

10116

Figure 12-31.—Construction of typical reflex klystrons. (A) Mechanical tuning; (B) thermal tuning.

consideration. An understanding of the characteristics, limitations, advantages, and disadvantages of the various types of input circuits is quite helpful for proper analysis and maintenance of the circuit and the set.

The input circuit determines receiver sensitivity. If gain were the only consideration, the receiver could be made to respond to even the smallest signal by merely adding stages of amplification. However, every amplifier (in fact, every electronic circuit) introduces noise into the overall signal. Since the input signal to the receiver is usually the smallest signal to be found anywhere in the receiver, the noise characteristics of the input circuit are of the utmost importance.

NOISE IN RECEIVERS

There are many types of noise generated outside the receiver. These types enter the receiver along with the desired signal, and may possibly be eliminated by means of the selectivity of the set. In this section, only those noises created within the receiver will be discussed. Included in the discussion will be the

Figure 13-8.—Directional lines.

along quite smoothly and rhythmetically from one object to another, grouping and relating objects which belong together, or the movement may be abrupt, creating lines that clash. This latter method is appropriate when drawing a scene of violence or conflict. Directional lines may be strong or subtle, but they should always lead the viewer so that he will see the things you want him to see. Figure 13-8 illustrates the use of directional lines. When you are planning a picture, make it a point to study the line directions in your rough sketch. Decide whether or not your main lines lead the viewer to the proper portion of the picture area. Ask yourself "Do the background lines interfere with the directional lines leading to the center of interest?" and "Are the lines crowded together or, equally undesirable, spaced at monotonous equal intervals?" Questions like these will help you to get the most out of the lines in your pictures.

VALUE

Value, the lightness or darkness (see ch. 16), should be consistent within a picture. The viewer will be attracted to the area where there is the greatest contrast of values. This phenomenon occurs because objects become more conspicuous when placed next to a value which contrasts with its own value. If on the other hand, an object is surrounded by values which are nearly the same as its own value, the object is not as likely to attract much attention.

Before you start a drawing, you should decide on a basic value pattern. The basic value patterns of most pictures can be reduced to one of the following four patterns: (1) light against dark, (2) dark against light, (3) dark and halftone (in-between tone) against light, and (4) light and dark against halftone.

Small value sketches, similar to thumbnail sketches, are excellent aids to use when deciding on a value pattern. These sketches enable you to quickly see a number of different value patterns. You can place them close together to see which one offers the best possibilities for a good value composition. Examples of the four basic value patterns are shown in figure 13-9.

PROPORTION

The three remaining principles of composition, proportion, balance, and clarity, are used most often when designing posters, pamphlets, or other similar material.

Figure 13-10 shows how a rectangular area can be divided into different proportions to lend more interest to the illustration. Notice that the rectangle divided into a number of equal squares is less interesting than those adjacent to it. Its proportions are less interesting because it is relatively monotonous.

In figure 13-11, rectangles with interesting proportions are shown in different tones. A black, a white, and a medium gray are used.

10117

LIGHT AGAINST DARK

DARK AGAINST LIGHT

HALFTONE AND DARK AGAINST LIGHT

LIGHT AND DARK AGAINST HALFTONE

Figure 13-9.—Value patterns.

Figure 13-10.—Proportion.

This type of treatment works well on a layout for a pamphlet cover. Whenever several tones are used, the layout will be more interesting if one of the tones clearly dominates the others in size or intensity.

BALANCE

A very important composition factor is balance; the placement of the various objects in the picture area so that the composition will appear to be fairly symmetrical. There are two general classifications for balance; symmetric and asymmetric balance, commonly referred to as formal and informal balance.

Formal Balance

Formal balance is obtained by placing each element squarely on an imaginary central vertical line, or by duplicating on one side each mass, shape, or line that appears on the other

10118

Figure 13-11.—Rectangle divided by tones.

side of the vertical, and at a corresponding position. The result is considered perfect symmetry. An example of formal balance is shown in figure 13-12.

Formal balance is commonly used today in layouts, illustrations, and advertisements in which the subject matter calls for reserve and dignity. For example, the use of formal composition and balance in the advertisement shown in figure 13-12, is fully justified by the subject matter.

Another example of formal composition and balance is found in the religious paintings from the period of the Italian Renaissance. A great many of these are composed by having a pyramid effect in the center of the picture area. The basic pyramid composition lends dignity to such paintings as da Vinci's "Holy Family."

One disadvantage of formal composition and balance is that when it is handled without taste, it may be merely ordinary. Each element should be studied in relation to the others and carefully placed. A pleasing balance should also be maintained between the top and bottom of the picture area. The picture should appear to be balanced when viewed from any direction.

Informal Balance

The use of informal balance permits greater variety and design; however, the problem of balance becomes more complex. The left side of the page should still balance the right side and the bottom half of the page should still balance the top half.

Informal balance is the balancing of the elements over an imaginary central vertical, but in an unsymmetrical manner. For example, a large or heavy mass placed on one side of center may be balanced by a small one placed further away from center on the other side. Do you recall when you were a youngster and played on the teeter-totter? It is likely that you teetered with another person who was much heavier than you. You did it, but how was it done? The heavier person simply moved closer to the fulcrum (the point on which the board rested). The same principle applies in the case of the heavier mass on one side and the lighter or smaller mass on the other. See figure 13-13.

When using informal balance, you must depend to a great extent on your sense of balance; no mathematical rules apply. The more elements to be arranged in an informal layout,

Figure 13-12.—Formal balance.

10118
10119

Figure 13-13.—Informal balance.

the more involved balance becomes. The layout must be balanced for shapes, masses, and color. Unless quite large in area, color should not appear in one part of the layout without being reflected elsewhere. For instance, if all blacks were placed in the upper half of the composition and all light elements below, the layout would seem to be separated into two unrelated parts.

In informal balance, a small dark element can be used to balance a large light element. Examples of this kind of balance are shown in figure 13-14. The optical center of an informal layout is also slightly above the actual center. When an element is placed at the exact center as it is in figure 13-14b, it does not appear to be as well balanced as an element placed slightly above the center as shown in figure 13-14c.

UNITY

Unity in a layout is the combining of the elements into an organized pattern which tends to weld the elements into a unified whole. In designing layouts, it should always be remembered that "the whole is more important than any of its parts." A composition without unity appears to be falling apart and produces a disturbing effect. However, it is possible to group the elements in an irregular manner to provide interest and variety. This is accomplished by allowing more white space around the outside edges of an arranged group of

Figure 13-14.—Small dark against large light element.

elements rather than between each individual element. This white border will bring the various elements together; it has the same effect as a frame.

The layout in figure 13-15a is disorganized and seems to be falling apart due to the great amount of white space between the elements. The layout in figure 13-15b, with less white

10120

Figure 13-15.—Unity.

space between the elements, is better constructed and has a more unified effect.

Crowding of the elements is as great a fault as having too much separation between the elements. The unity achieved depends greatly upon your sense of proportion.

CLARITY

The last composition factor which we will discuss here is clarity. Clarity defines elements; guards against blending elements to the extent of making them confusing to the reader. Clarity is quite easily achieved in your layouts by maintaining legibility in lettering and definitiveness in composition. For example, if you lap one illustration over another so that it obscures the other too much for identification, or place a heading over a confusing background, you are not achieving clarity. If you choose to letter a message directly on an illustration, the lettering and the illustration should be in contrasting tones. If the tones of the elements are too close in value, such as brown and black, they will blend together and become illegible and confusing. When this happens, a point of confusion has been created which distracts the viewer from the rest of the layout. Examine every layout for clarity as well as for the other factors necessary for good composition.

FIGURE COMPOSITION

The people you show in your pictures, like the people in real life, must have feelings and emotions to appear realistic. In life, people express their emotions and express their actions with words. However, in your pictures, the people you draw can communicate only by expression and gesture. The appearance and action which you give your figures must enable your figures to tell everything.

The figures you place in your picture setting should be complemented by the setting. One of the most important points to remember when placing figures in a setting is to choose a setting which will help to explain and strengthen

Figure 13-16.—Comparison between inanimate object and the human form.

10121 10150

the figures actions. When you wish to see something more clearly or follow an action better in nature, you can move your eyes or head. However, for a picture, only a set view is possible for the viewer. Therefore, this set view should be presented so that it best clarifies the action.

There may be few or many figures in a picture; arranging each group size into a good composition has its own special problems as well as possibilities. You must work, in effect, as a stage director; selecting appropriate characters, costumes, props, lighting, and, most important of all, a view that is clear and effective. You must become aware that good figure composition is far more than drawing a few figures in some relation to each other or placing them within the four borders of the drawing. You should learn to create a sharp and meaningful statement about a situation, and convey the various feelings of the people shown to be involved in the situation.

Figure 13-17.—Five mood symbols.

10122

THE LIVING, CHANGING SHAPE OF THE FIGURE

The drawing in figure 13-16 shows the striking difference between the human figure and the fixed forms of inanimated objects. The human figure is a living, mobile form which constantly changes shape. It can stretch, curl, lean, bend; the figure can assume countless different variations in form as it changes position.

It is this dynamism which provides a great deal of the interest to a picture containing human figures. Whenever you put two inanimated objects in a picture, no matter how much work you put into their construction, they will remain inanimate objects with no movement to add excitement and interest to the picture. But when you place two figures together, they will immediately appear to be related and to be responding to each other. They may also appear to be talking if placed face to face, or may appear to be looking at the same scene or object if both are shown facing in the same direction. The meaning of the picture will change as the attitudes or gestures which you give the figures change. The figure can be made to express any one of the human emotions or actions.

Mood Reflected by the Figure's Action

Earlier we noted that the head and the hands are the most expressive parts of the figure. However, the body can also express emotion. You can show feelings and emotions by drawing

Figure 13-18.—Experiments to find best descriptive layout.

10123

periment with the placement of the figures in different positions so that you can better determine the most clear and expressive way in which you can arrange them.

The Simple Setting

Most compositions include a place as well as people. It may be anywhere, the corner of a room or a vast forest. You may show a small portion of the setting or a great portion, and permit it to dominate the picture.

The role of the setting varies greatly. Often it simply serves as a background which orients us to the figure's location. However, in many pictures the setting has greater importance; it serves to emphasize the figure's mood and action. Figure 13-19 illustrates the effect of simple settings used to advantage. Whether the background plays a large or a small role, you should use it to strengthen and explain the action of your figures.

Adding Another Figure

When you add another figure to a setting which contains one figure you create a human relationship. Your task is to make the relationship between the figures clear to the viewer. As before, the setting should help explain the story, it should not interfere with the relationship of the figures.

Adding a second figure to a picture area often means that you must vary the size and depth factors. See figure 13-20.

THE APPROPRIATE SETTING

Whenever you start a picture which contains figures, you should have in mind a background which will contribute to the mood and action of

Figure 13-20.—Adding second figure to the simple setting.

10125

the picture. The scene should also be viewed from the view which best reinforces the impression you are creating.

For example, a light love scene could be more convincing by using a light, pleasant background. The same scene could be misleading or confusing if set against a dark dramatic background because the background would not support the intended mood of the scene.

Of course, events do occur in surroundings which are not generally thought to be appropriate to the event. However, from the picture compositors viewpoit, these are unusual events which would not be readily recognizable in a picture. Your task, as an illustrator, is to make the picture consistent throughout; both the background and the figure should support each other.

MAKING THE FIGURE STANDOUT IN SCENES

Often, the purpose of a picture is the setting. In such cases, you must give the setting the prominence it deserves, but also prevent it from overwhelming the figure. Size, position, value, and contrast are the most effective means to keep the scene from overwhelming the figures involved.

THE BORDERS

You should remember that there is a larger world outside the picture frame. Your placement of figures and objects should convince the viewer that the picture is part of the real world. Also, you should not forget that the borders are a part of the picture and often the link to the real world. The borders can have a particularly strong effect when you are using figures in your composition.

The effect of the borders may be to define or confuse, depending on where you place the figure relative to the borders. If, for example, you place a figure too close to a border, the figure may be obscured by the border; the composition is attracting the viewer's attention to the border rather than the figure's action. Even when the figure does not touch the border, the figure's gestures may direct the viewer's attention to the border. If a figure is placed nearer one border than the others, it tends to attract attention to

Figure 13-21.—Effect of border on actions of the figure.

10126

types of noises, their sources, methods of prevention or elimination, and "noise figure."

In all materials at normal temperatures, random movement of free electrons exists. The better the conductive qualities of the material, the greater is the random movement. An increase in temperature results in increased motion. In a conductor, this random electron motion results in erratic voltage fluctuations, called THERMAL NOISE because of the effect of temperature. Although thermal noise operates through a range of frequencies centered about the resonant frequency of the circuit, it is relatively independent of frequency at radar frequencies. Within normal temperature ranges, the noise spectrum decreases rapidly with increasing frequency; but this occurs noticeably only at and above the far infrared region of the electromagnetic spectrum. All random motion of electrons ceases at absolute zero temperature. At other temperatures thermal noise exists in all materials, but it is most important in conductors.

In electron tubes, electron emission from the cathode is not uniform in density or in time. Transit time of electrons is also nonuniform. As a result of these nonuniformities, electrons strike the plate at random intervals which are independent of the input signals or of the desired outputs. This phenomenon is known as SHOT EFFECT NOISE, or simply shot noise. Operating electron tubes in the space charge limiting portion of the operating range of the tube tends to reduce the effects of shot noise. The same problem exists in all electron tubes, and also in crystal diodes, transistors, and other current carrying devices.

In multigrid electron tubes (such as tetrodes, beam power tubes, pentodes, etc.), shot noise results in a random distribution of current between plate and screen. The additional noise which results is called PARTITION NOISE, and explains why pentodes are generally noisier than triodes.

Electrons in transit from the cathode to the plate in an electron tube induce currents into the grid circuit. If the electron flow were uniform, the electrons approaching the grid and those leaving the vicinity of the grid would have opposite effects, and would cancel each other. However, due to the random characteristics of the electron flow, the induced current is also random. The resulting noise is called INDUCED GRID NOISE. By the introduction of a proper mismatch, a reduction in the noise may be realized due to cancellation of part of the shot noise by a part of the grid noise. Only a small portion of the total noise may be eliminated in this manner.

Crystal diodes, when unexcited, will produce thermal noise the same as any other material. When current flows through the crystal, the result is a combination of thermal noise, shot noise in the barrier, and another noise (called FLICKER NOISE) which varies in magnitude inversely with frequency. This effect also occurs in transistors and in the oxide coatings of electron tube cathodes. It is most important at low frequencies. In crystal diodes, the effect of the combined noises is referred to as the CRYSTAL NOISE. TRANSISTOR NOISE is effectively the same as crystal noise, but occurs in transistors.

The NOISE FIGURE (or NOISE FACTOR) of a receiver is calculated by dividing its input signal to noise ratio by its output signal to noise ratio. Since the noise varies with temperature, the noise figure is usually expressed at a standard temperature of 63°F. The noise figure is expressed sometimes in decibels, and sometimes as a number. The smaller the number, the better the receiver.

Amplifiers connected in cascade will normally have a higher total noise figure than any of the individual amplifiers. The noise generated in the first stage will be introduced into the second, and amplified along with the desired signal. In addition, the second stage will generate noise of its own, to be further amplified by succeeding stages. Therefore the second stage also should have a low noise figure, although the noise figure of the first stage is the prime determining factor in receiver sensitivity.

LOW NOISE RF AMPLIFIERS

Conventional design of superheterodyne receivers calls for an RF amplifier as the input stage preceding the mixer stage. Due to the noise considerations just discussed, however, the use of the preamplifier at the microwave frequencies has been found impractical. It has been common practice to use the mixer as the input stage, with no RF amplifier preceding it. Recent developments in low noise devices, however, permit use of amplifiers based on these devices as input stages for microwave receivers. The devices discussed in this section are the triode RF amplifier, the traveling wave tube, the backward wave amplifier, the klystron, the

1010

the nearer border. This effect is shown in figure 13-21. To avoid this problem, you should learn to leave more space between the figures and the border. Proper placement of a figure greatly aids in creating the illusion of action and movement.

COMPOSING A PICTURE OF A GROUP OF PEOPLE

The principle which we have used for composing one, two, and several figures in a picture are the same principles we will use to arrange a whole crowd of people in a picture. This is because, in general, a crowd is little more than one or two expressive figures shown many times in various attitudes. If you can compose a few figures together in a picture, you can compose any number of figures in a crowd scene.

A crowd, like an individual, may express any emotion; gaiety, sorrow, anger, or tension. Its mood can be a more subtle one, too, it may be indifferent, mildly curious, or merely waiting for something to happen. A large group of people must always express some mood or feeling; a crowd is never expressionless.

Although every figure in a large group usually reveals the same basic emotion, they may do so in various ways. Study a real crowd or a photograph of one, note their different gestures and expressions. Unless you are aware of these individual variations and show them in your pictures, crowd scenes will tend to become monotonous repetition of forms and faces; a caricature rather than a convincing representation. Figure 13-22 illustrates the use of variation in a crowd scene; the individuals showing different forms of the same basic emotion.

SHARPENING THE EFFECT OF THE PICTURE

A composition may be well balanced, pleasant, and interesting, but the picture may still fall short of being effective. Usually this is a

Figure 13-22.—A picture composition of a crowd.

10128
10127

sign that the illustrator has not given enough thought to sharpening up the picture idea, thought as to how he can get his idea across faster, more clearly, and with the greatest impact.

After you have composed a picture, sit back and ask yourself the questions, "Does this arrangement really do what I want it to do?" "What would happen if I made one figure smaller and the other larger?", "Would the whole idea be clearer if I moved these figures closer together?", and "Do I need to show this much background?"

The time you spend in thought, asking and answering questions like these, is important. This type of directed thought often can mean the difference between a picture which is merely pleasantly composed and one which effectively expresses it's meaning.

10128

CHAPTER 14

PERSPECTIVE FOR THE ILLUSTRATOR

In chapter 11 you were introduced to perspective and to its importance in the realistic illustration of basic forms. Perspective is the art of drawing an object so that it will appear to recede in distance and create a realistic illusion of depth. Perspective is a natural phenomenon which is easily recognized with regular man-made forms such as railroad tracks, signs, fences and houses. Perspective gives the true length and direction of a receding edge or a receding side of an object. The principles of perspective apply to all forms. Perspective control of all free forms such as trees, clouds, mountains and people is equally important to the visual correctness of a drawing if the drawing is to look normal to the viewer.

Chapter 11 introduced the meaning and use of the horizon line and the vanishing points. The third element in perspective is the station point, the point from which the object is observed. These elements are shown in figure 14-1.

In learning perspective, the cube is the most important single object to study at the outset. When you thoroughly understand the principles of drawing the cube in good perspective, you can easily apply this to all other types of forms in perspective, for you will find as you progress into more complicated structural developments

Figure 14-1.—Third element in perspective.

10129

that relating them to the basic geometric form is the fastest, most accurate method of perspective drawing. Figure 14-2 contains some cube construction exercises that you should study carefully.

Although perspective is a useful tool, it should not be a substitute for careful observation. You may find it necessary to distort the perspective in order to create a more dramatic or realistic drawing. In all final analysis, observation and experience will tell you if a drawing is correct or not, but a thorough understanding of perspective will equip you with a more acute sense of observation and feeling for form and will help you in making your drawings more convincing and realistic.

THE PICTURE PLANE

A simplified definition of the picture plane is that it is an imaginary vertical plane placed

Figure 14-2.—Cube construction.

10130

between the eye and the object to be drawn. This is seen in figure 14-3. The object being viewed will appear on this imaginary plane just as it will appear on the finished drawing. The location of the picture plane between the viewer and the object will influence the relative size of the object on the finished drawing. The closer the picture plane to the object, the larger the image appears. Figure 14-3a shows a picture plane. You can see the eye level and the object being viewed. Between the eye and the object is the imaginary picture plane. Figure 14-3b shows the object as it appears to the eye of the viewer. The perspective lines have been extended to the vanishing points and the object now appears as it would when seen from the eye level or station point of the figure in 14-3a.

SKETCHING METHOD

The placement of the station point (SP) has more effect on the appearance of an object than any other element of perspective drawing. The station point should not be placed too close to the object or the drawing will appear distorted. Distortion should always be avoided. Whenever the station point is changed, regardless of how slightly, all perspective lines on the drawing change.

When you start a drawing, make several rough sketches to establish the best view for your needs, thereby establishing the best station point.

If a drawing requires accurate perspective, sketch freehand the desired view. Establish eye level and vanishing points and make any adjustments necessary. Figure 14-4 shows various steps in the normal layout of an object in perspective.

THREE TYPES OF PERSPECTIVE

In drawing simple objects, you will find that one, two or three vanishing points may occur. With complicated forms, there can be more than three vanishing points; these are called compound forms, which are discussed later in this chapter. At present, we are interested only in one-point, two-point, and three-point perspectives.

A Picture plane in relation to viewer and object.

B Object as seen by viewer.

Figure 14-3.—Picture plane.

10130 10131

Figure 14-4.—Layout in perspective.

ONE-POINT PERSPECTIVE

One-point perspective exists when two dimensions of an object (height and width) are parallel to the picture plane. This occurs when the object being observed is straight in front of the observer, not at an angle. In such a view there is only one dimension, depth, that is left to be accounted for. This dimension must have a a vanishing point. The two dimensions parallel to the picture plane have no vanishing points. Figure 14-5 shows how one-point perspective can occur in several ways. If you look at a cube straight on, the vanishing point is out of sight behind it. If you were standing inside the cube, as in a room, you would have the same situation that you have when you are looking down the middle of a street. The right and left walls of the enclosure correspond to the flat fronts of the buildings on the side of the street. In such a view all parallel lines appear to run to one vanishing point, except of course, the lines parallel to the picture plane.

TWO-POINT PERSPECTIVE

In two-point perspective, height is the only dimension parallel to the picture plane. This leaves two dimensions, depth and width, which must have vanishing points; thus two vanishing points must be established on the horizon line as shown in figure 14-6. In figure 14-6, the closer together the two vanishing points are, the less you see of the sides of the object being drawn.

When laying out a perspective drawing, follow the steps given in the SKETCHING METHOD. This will help you in deciding how much of the surfaces you wish to show in your drawing before you establish the two vanishing points. This procedure will automatically fix the station point and the view you wish to have. The vanishing points may be as close or as far apart as you wish, but remember that the closer together they are, the greater the chance of distortion. In figure 14-6 you can see that the horizontal edges of the cube become diagonals when drawn

Figure 14-5.—One-point perspective.

Figure 14-6.—Two-point perspective.

10133

in perspective. The angle of these diagonals is determined by the closeness of the eye to the object. The closer the eye to the object, the more acute the angle becomes.

THREE-POINT PERSPECTIVE

Three-point perspective occurs when none of the object's surfaces (height, width and depth) is parallel to the picture plane (see fig. 14-7). Three-point is usually needed when the station point is close to the object, such as when you are looking up at a large nearby ship or tall building. The horizon in this case is usually very low, or entirely below the object. If you were looking down from above, the horizon may not appear in the view at all.

A good general rule to follow when doing this type of perspective is that small objects will usually look better if the three vanishing points are well separated. The perspective should not be acute. To emphasize the bigness of an object, sharp diagonal lines are important. Here the closeness of the vanishing points strengthens the bigness effect.

The horizontal diagnonal lines must end at the eye level line. One line cannot be higher or lower than the other. Regardless of their distance apart, they must be established on the same eye level.

HOW TO DRAW A CUBE IN PERSPECTIVE FROM A PLAN VIEW

In order to place a cube in accurate perspective in relation to a definite station point and eye level, a plan view is used as shown in figure 14-8. Application of this method enables you to draw an object as it may appear at any distance and viewpoint you desire. The sources of information necessary for this type of drawing are a scaled drawing of the top and a side view of the object. In regard to drawing a cube, all sides are of equal length and a side view is not necessary. If a box of unequal sides were used, you would need an elevation view of the box in order to find its height. This is covered later in this chapter.

In figure 14-8 two-point perspective is used since only one dimension-height is parallel to the picture plane. Figure 14-8 has you looking directly down on top of a cube. Since the top of the cube is a square, draw a square on paper and establish the station point at a distance (A) no less than three times the length of one side of the cube away from the cube (fig. 14-8). The station point is the spot from which you will view the cube to make the drawing. Now place a horizontal line (B) (picture plane) between the station point and the square so that the line touches the nearest corner of the cube. It is not

Figure 14-7.—Three-point perspective.

10134

Figure 14-8.—Using plan view when one dimension is parallel to picture plane.

essential to place it here; it may be placed at some other distance from the cube, but it has been placed in this position for the purpose of measurement, which is dicussed later in this chapter.

Draw lines (C) (fig. 14-8) from each corner of the square to the station point. (Each corner of the cube represents the positions of a vertical corner of the cube.) The positions of the verticals on the picture plane are determined by the points of intersection of these lines with the picture plane. In order to determine the width of each side of the cube, drop vertical lines (D) from the points where the lines (C) intersect the picture plane. Make a heavy line (1) the same length as lines (a) or (b). Line (1) represents the corner of the cube closest to you. Because the corner of the cube touches the picture plane, line (1) representing the corner of the perspective drawing, will be the same length as it is in the plan view.

Now draw the eye level or horizon line (E) so that line (1) overlaps it. (If you want to look down on the cube, place the eye level above line (1); and below line (1) if you want to look up at the cube.)

Now draw lines (a') and (b') parallel to lines (a) and (b), extending them upward from the station point until they touch the picture plane. From these two points on the picture plane drop verticals (F) and (G) to the eye level line to establish the left and right vanishing points. To finish the drawing, draw lines from the top and bottom of line (1) to each vanishing point and then heavy-up the portions of lines (D) which represent the right and left edges of the cube.

Figure 14-9 shows how the same cube in figure 14-8 is drawn in perspective when two dimensions are parallel to the picture plane. Again you are looking directly down on the top of the cube in the plan view. The nearest side of the cube touches the picture plane. To establish the near corners in the perspective drawing, drop perpendiculars (A) from the corners in the plan view. To establish the far corners, draw two lines (B) from the station point to the far corners. From the points at which these lines intersect the picture plane, drop perpendicular lines (C). The positions of the far corners are at the intersections of these perpendiculars with the side lines (D) which go to the vanishing point.

MEASUREMENTS IN PERSPECTIVE

In drawing any object, proportions must be correct; and this is particularly true when you are drawing objects in perspective. In order for you to solve practical problems in artistic perspective, you must become acquainted with the methods of measurement. There are several ways to achieve these measurements, but we will cover only a few of the more important and most frequently used methods which may be applied in various ways.

Start by establishing the needed vanishing points and the station point. Establish the overall shape correctly before you continue on, or you may wind up doing endless correcting.

To divide a square, draw diagonal lines from corner to corner as shown in figure 14-10;

10134
10135

Figure 14-9.—Using plan view when two dimensions are parallel to picture plane.

Figure 14-11.—Dividing diagonal areas.

10136

reactance (parametric) amplifier, the maser, and the tunnel diode.

In addition to the low noise figure already discussed, the input amplifier must have certain other characteristics in order to be wholly effective. The circuit gain must be adequate to overcome the noise which is introduced by the succeeding stages of the receiver. It must be able to withstand the transmitter power leaking through the TR circuit; it should be conveniently small and rugged, and not excessively complex; and it should be as reliable and troublefree as possible.

The Triode RF Amplifier

In the UHF range, it is usually advantageous to precede the vacuum tube mixer by one or more stages of radiofrequency amplification at the carrier frequency. Vacuum tubes are able to withstand relatively large amounts of transmitter power, so the TR circuit is not quite so critical as with the crystal mixer type input circuit to be discussed later in this chapter.

The input circuits of UHF receivers usually employ disk seal triodes and are frequently connected to form a grid return type of circuit. An RF amplifier employing a disk seal tube in a grid return circuit is very stable and has very little tendency to oscillate, the only feedback path being through the extremely low plate to cathode capacitance of the tube. Pentodes are available for operation in the UHF range, but they generally have a higher noise figure than triodes and are therefore less suitable in applications where a high degree of sensitivity is required.

In VHF receivers that operate at 200 megacycles or below, the tuned circuits of the input stages are composed of lumped inductances and capacitances. Often physical capacitors are unnecessary, the inductors being made to resonate with the tube and wiring capacitances. In the region of 1,000 megacycles the lumped-parameter resonant elements are replaced by cavity resonators.

An example of an input circuit of a receiver that operates in the vicinity of 1,000 megacycles is given in figure 12-32. The circuit consists of a single stage of radiofrequency amplification, a local oscillator, and a mixer. Lighthouse tubes and coaxial line resonators are employed in each unit, and connections between units are made by means of short sections of coaxial cable. The lighthouse tubes are shown mounted in their respective tuners in (A) of the figure.

The RF amplifier is similar in construction to the lighthouse tube oscillator shown in figure 12-10 and the local oscillator in figure 12-32 (A). The only major difference between the RF amplifier and the local oscillator shown in figure 12-32 is that in the amplifier the middle cylinder of the tuner is not cut away at the grid terminal of the tube. As shown in the local oscillator section of (A), the cutaway section of the grid line provides the extra coupling needed in the oscillator between plate and cathode lines. Since there is no cutaway section in the RF amplifier's grid line, the plate and cathode circuits are isolated except for the small interelectrode capacitance between the plate and cathode of the tube.

The plate supply voltage is conducted to the plate terminal of the amplifier tube V1 by means of an insulated wire which passes through the innermost coaxial cylinder. This cylinder, which serves as one conductor of the plate line, is coupled to the plate terminal through capacitor C1 in order that the tuner may be operated at ground potential. Inductor L1 serves as a choke to prevent RF signals from entering the power supply. The middle cylinder of the tuner connects directly to the grid terminal, and the outer cylinder fits over the shell of the tube, which is grounded. All cylinders are connected together by the shorting plungers in the plate and cathode lines. A bypass capacitor within the tube provides an RF connection between shell and cathode, and cathode bias voltage is developed across C_{k1} and R_{k1} in parallel between the cathode pin and ground. Input signals are coupled into the cathode to grid line by means of a probe, and a coupling loop is used to take the amplified RF signals from the plate to grid line.

An RF equivalent circuit of the amplifier, in which the plate and cathode lines are replaced by parallel LC circuits, is shown in the upper left portion of (B). Observe that the equivalent circuit is drawn so as to emphasize the grid return aspect of the amplifier. The plate line, represented by L_{p1} and C_{p1} in the figure, is adjusted to resonate with the plate to grid capacitance C_{gp} of the tube at the frequency of the incoming signal, and the cathode line in parallel with C_{gk} is adjusted very nearly to the frequency of the incoming signals.

1011

where these diagonals cross is the center of that surface of the cube. Each surface of an area can be divided as many times as necessary until you have the number of divisions desired. This is always a correct method, regardless of the perspective of the cube.

It is sometimes necessary to divide an area or a diagonal into a number of parts. The key to most division of space in perspective is the vertical or horizontal line parallel to the picture plane. For example, to divide a receding plane into square units, divide the left vertical in figure 14-11 into equal parts of desired measurement with a ruler, such as the seven parts shown. Run lines from the points of division on the vertical line out to the vanishing point. Draw a diagonal from corner to corner as shown, and the intersections of the diagonal and the vanishing horizontal lines are the correct points for the vertical lines to be added.

Figure 14-12 shows the correct method of dividing a rectangular area into uniform rectangular patterns, such as floor tiles. The width of the square is first measured on a horizontal line (A). Two vanishing points are established and lines are run first from the divided horizontal line to the left vanishing point, then the depth is established by running line (B) to the right vanishing point. A diagonal line is run from point (1) to point (2). Where the diagonal intersects those lines running to the left vanishing point are the correct points for the receding lines running to the right vanishing point.

Figure 14-13 shows how to draw vertical divisions in perspective, be they fence posts, telephone poles, or any object with even space

Figure 14-12.—Dividing rectangular area.

10137

Figure 14-13.—Drawing vertical divisions in perspective.

Figure 14-14.—Drawing the circle in perspective.

10138

between each member. The first two members are constructed with the desired space between them. Locating a vanishing point is accomplished by drawing lines (A) and (B) from the original two members. At no time should any of the posts extend above or below the receding lines. The center of the first member is marked and line (C) is drawn from the vanishing point through the mark.

From the top of the first member draw line (D) through the center of the second member. The third member will be located where line (D) touches line (B). Repeat this procedure to locate any number of members desired, doing one at a time.

DRAWING THE CIRCLE IN PERSPECTIVE

The circle is the guide for drawing all two-dimensional curves, ellipses and ovals in perspective. The base figure for drawing the circle is the square. The reason the circle in perspective is drawn with the aid of the square is that, while there are no direct measurements on a curve, vanishing points are easily determined for the square, and proportions of the curves can easily be seen within the square. Figure 14-14 shows the proper layout of a circle drawn in perspective. The first step in the layout is to draw a circle with the dimensions desired. Fit a square around the circle as shown in step 2 and add the diagonals and center lines shown in step 2. This will give you eight check points for drawing the circle in perspective. The circle in perspective will be an ellipse. The third step is to draw perspective lines back to the desired vanishing point as illustrated. The back line of the new square is determined by the method presented in figure 14-9. Now diagonal lines are drawn from corner to corner in the perspective square. Within the original square, short vertical lines are drawn downward to the picture plane from the points where the circle line and the diagonal lines intersect. From these two points, draw lines back to the vanishing point. The points at which these lines cross the diagonal lines in the perspective square are the points through which the curve of the ellipse is drawn.

The center of the circle shifts from the center of the square when the circle is in perspective. The intersection of the diagonals is the perspective center; the intersections of the horizontal center line with the outermost vanishing lines are points of the perspective circle. The major axis of the ellipse is on a horizontal line drawn through the exact center halfway between the top and the bottom of the ellipse.

When drawing ellipses it is often best to rough them in freehand and get the general shape desired, then relate the square in proper perspective superimposed on the freehand ellipse. This procedure is shown in figure 14-14. When the square is proportionally correct, cross the center with two diagonal lines and cross these with a vertical line through the intersection of the diagonal lines. Draw a horizontal line through the center to determine the perspective center. Use the vanishing point to have the direction of the receding lines correct.

THE CYLINDER

Figure 14-15 shows some of the applications of the circle in perspective when it is associated with the right circular cylinder. At the eye level the circular section line appears as a straight line. Above and below the eye level the circular sections appear as ellipses that become progressively more open as their distance above and below the eye level increases. The proportion of the ellipses—the proportion of short to long diameters—also depends upon the distance of the cylinder from the eye. The nearer the eye, the more open the ellipse; the farther the eye, the thinner the ellipse. When seen at a considerable distance the ellipses appear as nearly straight lines.

Another important point to be noted is that the long diameter of the ellipse is at right angles to the axis of the cylinder and both the axis of the cylinder and the long diameter of the ellipse point toward their respective vanishing points.

THE CONE

Think of the right circular cone as being enclosed within a cylinder, both having the same base and the same axis. Figure 14-16 shows the cone first on its side, then resting on its sloping side. Notice that the long diameter of the ellipse representing the cone's circular base has been drawn at right angles to the cone's axis, a relationship that is constant in the cone as it is with the cylinder. Figure 14-16 shows several examples of circular construction based on the shape of the cone.

Figure 14-16.—The cone in perspective.

10140

Figure 14-17.—Perspective drawing from plan and elevation views.

PERSPECTIVE DRAWING FROM PLAN AND ELEVATION VIEWS

When constructing a perspective drawing in exact detail, an exact detailed, scaled, plan view and elevation view are necessary. The first step is to establish the picture plane line. The plan view is arranged behind the picture plane with areas desired in the perspective drawing facing the picture plane as shown in figure 14-17. The lines of the plan view that you desire to be of true scaled height should rest on the picture plane; for example, the left front corner in figure 14-17. Arrange the elevation view to the left and below the picture plane at the level you desire for the perspective drawing to be. Select a station below the approximate center of the plan view. Keep the overall angle at 30° or less to avoid distortion. Now draw lines from the station point to the plan view corners of the important parts of the structure and any part you want to include in your perspective drawing. From the intersections of these lines with the picture plane, drop parallel vertical lines to establish accurately the widths of the different parts of the structure. These vertical lines are drawn down to a line level with the bottom of the structure in the elevation view.

Line (A) represents the closest point of the structure to you. This is the only line in the perspective drawing which is not foreshortened and is the only line that can be used for vertical measurements. You must now decide on the location for the eye level or horizon line. After you have located the horizon line, draw lines (B) and (C) parallel to lines (D) and (E)

10140

10141

Figure 14-18.—Compound forms in perspective.

in the plan view. From the points at which lines (B) and (C) intersect the picture plane, drop vertical lines to the horizon line and thus establish the right and left vanishing points.

The next step is to carry across vertical measurements from the elevation view to line (A) and draw construction lines from the points on line (A) to the vanishing points using the same procedure already discussed. The vertical lines dropped from the picture plane will automatically establish the width of windows, doors, walls, etc. in the perspective drawing. Remember, you can make direct vertical measurements only on line (A) in the perspective drawing because it is the only line of true length.

COMPOUND FORMS

Most objects consist of compound forms: the combination of different sized cubes, rectangles and ellipses. Using the methods of construction already covered, you need only reduce the compound forms down to their basic simple forms and construct the drawing one step at a time. Figure 14-18 shows how complex designs of compound forms are reduced and, using what has been presented, are laid out in a drawing.

FORESHORTENING

When an irregular object, such as the human arm, recedes toward or away from the viewer it

Figure 14-19.—Foreshortening the figure.

10142

Figure 14-20.—Figures in perspective.

is foreshortened. It is then in perspective. Within the irregular or "free forms" there may be many curves—this makes good foreshortening difficult. The only cure is knowledge and practice, and a great deal of practice in drawing the figure in various positions as mentioned in chapter 12. The principles of measurement that are applied to geometric forms can be used to advantage in foreshortening the figure. In figure 14-19 these principles have been applied in determining how much or how little is seen of the head of the figure lying on the floor with the feet diagonally toward the viewer.

In some unusual views, it is helpful to fit the figure into a rectangular form which will enable you to quickly determine if and where a part will be seen and in approximately what shape. You will find that perspective can be the cure for many problems you may run into when drawing all types of objects. Again, you must remember to give careful consideration to the location of the station point so that distortion will be minimized and to the distance apart that you set the vanishing points.

DRAWING THE FIGURE IN PERSPECTIVE

The correct placement of the figure in a perspective drawing is a must. Because people are all approximately the same size, the viewer of any picture will automatically relate the proportions, scale and sizes of all forms in the picture to the figure.

Proper use of the vanishing point is the main consideration in placing figures correctly in perspective. The vertical distance between the receding guidelines to the vanishing point is used to establish the height of any figure anywhere in the picture. To place the figures to the right or left of these guidelines, horizontal lines from the head and feet are drawn off the guidelines as shown in figure 14-20. Once you have determined the height of one figure, the correct height of all other figures is automatically taken from the intersection of the two

Figure 14-21.—Reflections in perspective.

10143

S6101

Figure 14-22.—Shadows in perspective.

horizontal lines and the receding lines going to the vanishing point.

REFLECTIONS AND SHADOWS IN PERSPECTIVE

REFLECTIONS

An object reflects as far below a reflecting surface line as it projects above the reflecting surface. Reflection is not a reverse of the scene being reflected. Although the eye level remains constant, the view is a reflected one. When the eye level is above an object, you are looking down at the object and, since the object is reversed in a reflection, the proportions remain the same—but you are now looking up at the object. Refer to figure 14-21. When the object being reflected is close to the eye level, the reflection is nearly a duplicate in reverse, but not so when the object is well below the eye level.

SHADOWS

Light travels only in straight lines. From an established light source, lines are drawn to touch the corners of a form and are continued until these lines touch the surface of the plane on which the object is resting.

All shadows recede to the same vanishing point when there is a single light source. The shadow's vanishing point will fall on the horizon line directly below the source of light. Shadows follow the contour of the plane on which they fall as shown in figure 14-22.

10144

CHAPTER 15

ADVANCED LINE AND TONAL PAINTING

Line drawings date back to the time of the cave dwellers of the Stone Age and, through the course of history, have been refined into a very precise medium of art. Line drawings were the only type of pictures that could be reproduced by the early printing presses. Even today, line drawings are widely used in newspapers, magazines, and other advertisement and visual communication fields because they are the least expensive of any medium to reproduce and will print well on almost any type of paper. The printing is done by means of a line plate.

Changes and corrections are very difficult to make on line drawings, so careful planning and compositional sketches containing overall value patterns and drawing details are essential in making good line drawings.

When using tonal mediums, you can duplicate the values of your subject tone for tone, but not so with line. You must translate these values into terms of the line mediums and simplify the number of values to avoid having a line drawing of an overall gray tone. This gives to the illustrator an excellent opportunity to interpret the

Figure 15-1.—Five basic line techniques.
(a) Ross Board technique. (b) Dry-brush technique.

(e) Crosshatch technique.

10145

Figure 15-2a.

subject in a highly expressive and personal manner.

Line drawings have been considered by some to be the most sophisticated of all mediums of art because there are no real lines around the forms in nature; just tones or values, colors and edges; but no outlines. But in line drawing, line is used to establish a form; the line is an arbitrary symbol which has long ago been developed for the purpose of artistic expression. Because the outline is an artificial convention, you must learn to handle it with skill if you expect to use it effectively.

You may use a line for three different purposes. First, you may use it to contain the subject, establising the contours within which the subject is understood to exist. Second, you may use the line to create the illusion of three-dimensional form and to suggest texture. Third, you may use the line with other lines to create a compositional pattern and to contribute life and movement to that pattern. Of all the rules and uses of any medium in art, remember, you must always retain the impression that you are depicting form. You must be careful not to lose the sense of solid form in your drawings or you will have nothing but meaningless lines on paper. No matter how cleverly you apply the lines, you will find that technique will not replace the necessity of retaining the form of the subject.

SAME SUBJECT-SAME TONAL EFFECT-DIFFERENT TECHNIQUES

A good knowledge of line techniques is basic to your illustrative career. With imagination, you can create the most intriguing effects with the simplest of tools. With practice and experience you can use one tool with such versatility that you can duplicate the effects in a drawing that was done with several pens or combinations of pens and brushes. In figure 15-1 you can see how the same subject was rendered in five different techniques.

Figure 15-1a illustrates the ROSS BOARD technique. ROSS BOARD is a special drawing paper having a fine pebble grain. When a black crayon is dragged across the top of the grain, the raised area becomes black, while the recessed space between the grain remains white. When the crayon is pressed hard against the board, the white spaces fill up and a solid black results. With this technique, a sable brush and ink is often used to do large, smooth, solid lines.

Figure 15-1b shows the dry brush technique. This technique is usually best accomplished if used on a course-grained paper. Solid areas are painted with a fairly wet brush pressed firmly against the paper. For shaded areas, the brush is used somewhat drier, and the brush is always tested on another piece of the same type paper.

10148

Figure 12-32.—Triode input circuitry.

Rossboard

Dry Brush

Stipple

Scratchboard

Crosshatch

Figure 15-2b.

10147

For the light tone areas, a comparatively dry brush is dragged across the drawing very lightly so that only the raised tooth of the paper catches the black ink.

Figure 15-1c shows a stipple drawing done with a rigid pen nib. The point is pressed lightly across the paper for the smaller dots and pressed heavier for the larger dot and the lines. This is another technique where a sable brush is used for heavier lines and solid black areas.

Figure 15-1d shows the scratchboard technique (which is described in greater detail later in this chapter). A special scratchboard paper is used as the basis for this technique. A solid ink background is brushed over the whole area with a chisel-edged brush. White chalk is rubbed over the back of a preliminary pencil sketch and the drawing is traced down on the scratchboard with a hard pencil. A needlepointed tool is used to scratch out the fine lines and a square-pointed tool to scratch out the heavier lines. With this technique, a limited number of corrections can be made if mistakes occur.

Figure 15-1e shows the crosshatch technique, the oldest and most effective technique for creating tone. The secret of effective crosshatching lies in the careful control and knowledge of the exact number and character of lines needed to create tone of a given value. A flexible fine nib pen is most commonly used for this technique. When a wider line is needed, the nib is spread apart by pressing it harder against the paper.

The same principles which applied to the construction of the head in figure 15-1 also apply to the drawing of a figure or a group of figures. The figures in figure 15-2a are rendered in a variety of different values, techniques and textures, but in each case the basic form is the same. The same approach to form and value exists when individual forms are combined to form a composition as in figure 15-2b.

SELECTING THE TOOL

After deciding precisely what effect you want to create in a line drawing, you should select the drawing tool that will give you the desired result, if not precisely, then as nearly as possible. It is important for you to become acquainted with some of the most useful tools and the effects possible by using them. In this way, when you know that a certain tool will make a particular design, you can often plan your composition with that tool in mind.

With experimentation you will find many worthwhile effects beyond what is shown in this book. A good illustrator constantly experiments to find new and interesting effects with all of the tools and instruments available to him.

Figure 15-3 contains several examples of one subject rendered with several different tools and combinations of tools.

SCRATCHBOARD TECHNIQUES

A relatively new technique in the medium of line is the scratchboard. This technique of line drawing reproduces very well, even when greatly reduced, and requires the simplest of drawing tools for its construction.

Figure 15-3.—Different tools and combination of tools.

10148

Figure 15-4.—Scratchboard drawing.

The excellent quality of line produced with the scratchboard makes this technique ideal for pictures requiring accurate and precise details.

Scratchboard drawings are easy to create once you understand them. The drawing is made on the special paper (called scratchboard) which is coated with a fine white clay.

A good, detailed preliminary drawing containing value patterns and exact details is essential with this technique.

To transfer the drawing to the scratchboard surface, the back of the preliminary drawing is coated with either white chalk or pencil, depending on the type of drawing being done. If the typical scratchboard method is used, white design against a black background, you use the chalk transfer procedure described earlier. If the pattern is to be a black design against a white background, the pencil transfer procedure is used and then the areas of black are inked in. A third method of scratchboard is to combine both methods mentioned. The pencil transfer is used to trace down the design. The black areas are inked in and then the design on the blackened areas is traced on the back by using the chalk transfer method. These three methods are shown in figure 15-4 along with the three basic scratchboard tools.

KEEP REDUCTION AND REPRODUCTION IN MIND

When you make your drawings larger than the final printed size will be, as is usually the case, you must consider what will happen when the picture is reduced for reproduction. A drawing reduced to one-half of its original size will be reduced proportionately; both the lines and the spaces between the lines are reduced in size.

Figure 15-5a shows a drawing made with reduction in mind. Figure 15-5b was made without allowing for reduction. In drawing A all of the fine lines hold up. In drawing B many of the finer lines are "dropped out" and some sections have "filled up", leaving solid black areas where crosshatching is desired. This is the result of having the lines too close.

ADVANCED TONE PAINTING

Tone is the best medium for creating a convincing illusion. With tonal mediums you can duplicate the entire range of values and textures found in your subjects and render realistic or naturalistic pictures. Any value can easily be mixed, and thus you have complete control of the variety of edges which delineate shapes; you are not limited to just implying the existence of the edge as is the case when using lines. Tonal mediums are the only practical mediums for use in making full color pictures, although a combination of tone and line can be used if the effects desired are more easily recognized when the combination is used. The tone and line combination is especially useful with the transparent tonal mediums.

Tonal paintings are reproduced by means of halftone engravings or are printed by offset

10149

Figure 15-5.—Keeping reduction in mind.

lithography. This latter is a fairly new development in the printing field, but it has been refined in the last few years to such a high degree that almost any tonal medium or combination of tonal mediums can be reproduced with complete accuracy by offset printing methods.

When working with tonal mediums, as with any medium, the first and foremost basic principle you must consider is to have a plan or method of procedure. Any drawing having many shapes and tones can easily get out of hand if a well-organized method of procedure is not followed.

It is best to build up a picture from start to finish in a logical, orderly manner. Most illustrators get the large, simple masses under control before working on any details in the picture. Establishing the pattern of masses and values at the beginning will help to express the mood or feeling of the picture at the start. Another basic principle is to keep all parts of the drawing developing at the same time. This helps in the overall control of the values and forms.

In tonal compositions the edges play a large part in your drawing,. and, next to shapes and values, edges are the most important thing to consider. You will find that hard, sharp edges tend to come forward and attract attention whereas the soft diffused edges tend to stay back and remain subordinate.

Since the goal of all illustrating is to create pictures which tell a story with interesting effects, there are no rules as to which mediums may be used together to achieve the effect desired; so constant experiment with the mediums and combinations of mediums is the only way to broaden your ability to use any and all mediums effectively. Constant experimentation is an absolute necessity in becoming a good illustrator.

Before you begin painting a subject in tone, you must study and analyze the value pattern of the subject thoroughly. This is easily done once you understand that there are three areas to look for: the subject's natural value, the light plane, and the shadow plane. The first to consider is the natural lightness or darkness of the subject (figure 15-6a). This tone remains about the same even with changes of light being cast on the subject. Of course, the values will lighten with a strong light or become darker with the absence of light, but the values will always change proportionately. You should always keep the basic value relationship consistent in your drawing.

10150

Figure 15-6.—Interpreting tones.

The next thing to analyze is the pattern of light and shadow that falls over the form. Establish or find the source of light and determine what part of the subject will be in shadow. The light should generally come from one direction only; but, in reality, there is usually a secondary light, which must be kept very weak compared to the primary light source. The secondary light is quite helpful for modeling the form in shadows, but it must never compete with the primary light or reality will be lost.

The planes facing the light source from the overall light pattern and the planes facing away from the light form the overall shadow pattern. These are easily seen when the subject is lighted from one direction with a strong, dominant light. The light and shadow pattern can be seen in figure 15-6b. When working with variations of tone within a shadow or light area, do not overmodel them or they will break up the pattern. Forms which are in the middle value range show the separation of light and shadow best. Figure 15-6c shows the tone, shadow and light patterns combined into a final rendering.

CONTROL OF EDGES

In tonal painting the edges can be hard or soft or of any degree between the two. When there is a hard edge, it means there is a sharp dividing edge between two tones of very strong contrast. A hard edge catches the eye and should be used to bring out important parts of the picture upon which you want to focus the attention and interest of the viewer. There can be a hard edge between two tones of close value, but this will not appear nearly as hard as when sharply contrasting tones are used.

A mistake frequently made by illustrators is that they tend to compose their pictures as though every form, figure, or shape were an entity in itself, entirely unrelated to any other shape in the picture. This causes an unconvincing pastedown look. Every object does have a definite tonal relationship to every other object; and this fact is best illustrated by correct handling of the edges. It is a mistake to bring out everything in your pictures. Do not be afraid to lose edges; a soft or a lost edge can be as powerfull as an edge sharply defined. Always keep your edges soft in

10150
10151
10151

the early stages of a drawing because it is easier to sharpen an edge than to soften one. However, you will find that a hard edge tends to appear soft when reproduced, and a soft edge may be lost altogether. Keep this in mind when your work is to be reproduced.

CASEIN PAINTING

Casein, a very old medium of painting, is one of the most versatile and interesting of the tonal mediums. When varnished, it is almost impossible to tell from a picture done in oils. Without varnishing, it retains a matte or dull surface similar to opaque water color.

Casein paints dry rapidly and can be used on almost any surface-paper, canvas, gesso panel, illustration board, or on Masonite. Thinner materials, especially light weight paper, tend to buckle and the thick casein may crack and chip off. The surface should be rigid enough for the thickness of the paint. Casein is very rough on brushes. Make sure the bristles are clean before you put the brush down.

The size and type of brushes used with casein is purely a matter of personal choice. You may find that, for large areas, a large brush is best; and, for finishing and detailed work, small sables are best. Bristle oil brushes can be used to create rough texture effects. Razor blades are useful to scrape out mistakes or smooth down areas where paint has piled up. A razor blade is also useful for creating interesting effects such as old brick walls or rough earth.

When it is desirable to keep some areas of a picture flexible and wet while other areas dry immediately, drying can be retarded by adding a few drops of SHIVA media varnish to the paint. Similar results can be achieved by mixing one-third oil paint to two-thirds casein. Water can still be used as a mixing agent.

Casein should not be squeezed out in a glob, but made in the shape of a "V" with a drop of water placed on the inside wedge, so that the pigment will not dry out too fast. At the end of the work day, or at anytime you have to leave your work for any length of time, place a damp cloth over the paint to keep it moist and ready for later use.

SURFACE PREPARATION

When working on a pure white surface it is usually difficult to gage the value of your tones. You may find it helful to apply a thin wash-like tone over the surface. The color used for this thin coat should be the color that is predominate in the painting. For example, if orange is the color most predominate, the wash coat should be a grayish orange. Care must also be exercised to avoid keying your pictures too low in value as well as too high. Figure 15-7 shows a drawing in casein.

Figure 15-7.

COLORED INK PAINTING

Painting with colored inks can give very satisfying results because they are easy to handle, with experience, and they are the most foolproof medium for color work to be reproduced.

Many different effects are available with other color mediums, but colored ink also has

10152

its own advantages which make it unique; (1) it is highly transparent, (2) while water soluble, it is waterproof when dry, and (3) many coats can be applied one over the other without any pickup of the previous coat, creating a rich luminous effect. This latter technique is called glazing, and the coats are called glazes.

The usual procedure of painting with colored inks is to lay a series of transparent color glazes over an underpainting. The underpainting is done with diluted black waterproof ink washes. The undercoating usually is done to a state resembling a finished black and white painting. The main differences between a black and white underpainting and a finished black and white picture is that all of the high-key areas that contain pure color receive no tone and are left for the pure color.

The colored ink is glazed over the underpainting layer upon layer, until the desired depth and richness of color are reached. With each layer, the color becomes richer and stronger; but, since the ink is water soluble, it can be diluted with water to any degree of desired intensity.

With time, colored ink paintings will fade; to protect against this, a coat of clear varnish can be applied over a finished picture. Besides its protective qualities, the varnish will add a surprising depth and richness to the painting.

10153

10153

CHAPTER 16

COLOR

As an Illustrator Draftsman, you will be called upon to use color in a large portion of your drawings. Before you can use color effectively, you will need to have a clear understanding of what color is, how color is organized, and how color can be employed to best advantage.

What is color? Where does color come from? We find that color is the sensation experienced through the eyes when the eyes are struck by light waves of varying lengths. There must be a light source before colors can be seen. When there is no light, there is no color. The sun gives off rays of light called "white light." This white light from the sun *contains all of the colors* that can be seen by the human eye. This is readily demonstrated when there is a rainbow, or when the rays of white light shine through a piece of glass called a prism. In 1667, Sir Isaac Newton, with the use of a prism, discovered that pure white light could be divided into different color wave groups.

In 1866, a scientist named Helmholz discovered that every color has three different qualities or dimensions; hue (name of a color), value (lightness or darkness of a color), and intensity (purity of a color). Because Helmholz did not work out any practical system for applying his theory, it was not until the turn of the century that an art instructor named Albert H. Munsell took Helmholz's theory and developed the complete system for analysis and organization of color that we have today.

When an object has color, it contains pigment, that quality which gives the object the ability to absorb certain rays of light while reflecting other rays. Light falling on surfaces differing in texture and consistency is reflected and absorbed in different ways. Since the absorption of light rays is never complete, the color of the object is never flat. Also, some of the white light is usually reflected as a highlight on the object. As a consequence, in nature a color is made up of a great number of hues, so that if an artist paints a red table with red pigments only, the painting will be dead in color compared with the real table. On the real table, many variations of light produce many subtle variations of hues, and the artist must paint the table with similar variations of hues, as well as values, if he is to represent the real table adequately.

Those materials which are especially rich in pigment are carefully selected and purified into the paints we use. When you work with these pigments, you are working with pure colors which have the special property of reflecting the particular color waves you want.

As an Illustrator Draftsman you will be most concerned with learning how to recognize, judge, and control the differences in these three dimensions of every color: hue, value and intensity.

COLOR ORGANIZATION

HUE

The word hue is the term used to name a color. Red, yellow, blue, violet, red orange, etc., are different hues. Each hue has its own place on the color wheel as shown in figure 16-1. The hues which are closer together on the color wheel are more related and are harmonious because they contain some part of the colors lying next to them. The more separated they become, the more distantly related they are until a color is situated directly opposite another; then it is referred to as a complementary color. Complementary colors have nothing in common, but are used to form sharp contrasts; or they can be mixed to create neutral grays.

10154

Warm and Cool Colors

The terms warm colors and cool colors refer to the qualities of the hues. In figure 16-1, you will see that the color wheel shows the primary colors: red, yellow and blue; the secondary colors: orange, green and purple; and the tertiary colors: yellow orange, yellow green, blue green, blue violet, red violet and red orange. These are in a ring labeled pure colors. You will note that the color wheel has been divided into two parts. Those colors on the left, centered around the hue orange are considered to be warm colors, while those colors on the right half of the wheel, centered around the hue blue are considered to be cool colors.

From the pure color ring toward the center, we see that colors are changed in value by adding black, thus shading the color. From the pure color ring outward, we see the primary colors tinted by the addition of white to the color, and thus lightening their value. We can see that though the values of a pure color may change, the hue remains the same.

You will also find that when a color, say a green, is seen fairly close to a yellow, it will tend to be warm, whereas a green further around the wheel toward blue will give the effect of being

Figure 16-1.—Color wheel.

10155

cool. When a hue leans one way or the other, it is referred to as a warm hue or a cool hue. This is true of all hues on the color wheel. All hues can be warmed by the addition of yellow, and cooled by the addition of blue.

Achromatic Colors

The neutral (white, gray and black) are achromatic colors and are considered to be colors in only a broad sense because they lack two essential color dimensions: hue and intensity. Black is far from being negative, because it affects the appearance of such hues as orange and yellow, turning them to brown and olive. The neutral colors are also useful in modifying the values and intensities of all other hues. The warmest black is ivory black and the warmest white is flake white; these are manufactured colors not producible by the illustrator from other usual pigments and materials.

VALUE

The second dimension of color is value, and is considered to be the most important dimension of color. Mistakes made in the choice of value are much worse than mistakes made in the choice of hue or intensity.

The word value refers only to the lightness or darkness of a color. The words tint and shade refer to the value of a color. To create a tint, you add white to a hue, to create a shade, you add black to a hue. In neither case has the hue changed, only the value has changed.

In order for you to handle color effectively you must be able not only to see and recognize the differences of value in your subject, but also to interpret those differences on your palette. Because the range of values in nature are far greater than your range of hues, you will not be able to merely match nature's colors with those on your palette. You can readily see that your purest white is many times darker than sunlight reflected from a shiny surface.

As an illustrator, you must be able to decide which area is the lightest and which area is the darkest, and then decide how light it is to be, or how dark it is to be. You must relate all of the other values around this decision. You must also decide if the area is to include the whole range of values from white to black. The choice should depend largely on the effect you desire to create. When a value range has been decided upon which appears to be appropriate, you should attempt to keep it consistent throughout the whole picture.

INTENSITY

The third dimension of color, intensity or chroma, refers to the strength, saturation or purity of a hue. A pure green, for example, will give the sensation of being greener than a diluted green because there is more pigment in the undiluted green, and it will have a greater ability to reflect the green rays of light.

Most colored pigments straight from the tube are of maximum intensity. You will seldom, if ever, use the colors in this pure state. The intensity of any color may be reduced by mixing it with black, white, gray or its complementary.

Colors become weaker in intensity as they change in value. As shown in figure 16-2, starting with purity at the center, the intensity of the three primary colors has been reduced by adding greater quantities of gray to the colors until we have reached an almost pure gray. The value of each color has remained the same, only the intensity has been changed.

We can easily observe this change in intensity in familiar objects around us. The color of a pair of dungarees is most intense when it is new, but the color becomes dull and faded and less intense after repeated washing of the dungarees.

Landscape colors lose their intensity when covered with fog, mist or smoke, but regain their intensity in brilliant sunlight. When colors are seen in the distance, they will have reduced intensity as compared to the same colors seen close up.

ADVANCING AND RECEDING COLOR

In creating the impression of depth in your pictures, you will find that warm colors will tend to appear to be nearer the viewer than will cool colors. As colors become less intense and lighter and grayer, they appear to fall off into the distance giving the feeling of atmosphere being between the viewer's eye and the object being viewed.

In figure 16-3 we see that the colors lose their intensity as they recede to the background. Although the soil is pretty much the same throughout the area in the picture, realism was added by reducing the intensity of the colors as they fall off toward the horizon.

10156

Actually, the cathode line is made slightly inductive in order that any feedback voltage supplied through the small plate to cathode capacitance C_{kp} (approximately 0.05 $\mu\mu f$) will have a phase opposite to that required to start oscillations. Thus the cathode line length is somewhat less than a quarter wave at the signal frequency.

Because the output coupling loop of the amplifier is located near the shorting plunger in the plate line, the output coaxial cable is shown as a tapped connection to L_{p1} in (B). The plate line thus acts as a resonant transformer to change the low input resistance of the cable (approximately 50 ohms, since the cable is usually matched at the far end) to a higher resistance across the entire resonant circuit. The value of load resistance across the resonant circuit is governed primarily by the bandwidth required for the amplifier. Since no provision is made for tuning the amplifier during its normal operation, the bandwidth must be wide enough to pass received signals despite slight changes in the transmitted frequency.

The tuned cathode circuit is loaded by the input resistance of the amplifier in parallel with a resistance representing grid loading effects and tuned circuit losses. The net resistance is matched approximately to the characteristic resistance of the input line by tapping the input cable to a point near the shorted end of the cathode line. The tap location is chosen for optimum signal to noise ratio and results in a resistance termination for the input line which is slightly more than its characteristic resistance.

Traveling Wave Tubes, Backward Wave Amplifiers, and Klystrons Used as Low Noise Input Amplifiers

Basic operation of traveling wave tubes, backward wave amplifiers, and klystrons has been covered earlier in this chapter. The low noise properties of these devices are obtained by the use of a specially designed electron gun. When the TWT is used as an input amplifier, a filter is normally employed to reject the image frequency. Without the filter, if the image frequency is allowed to pass, the noise power is doubled; but with the filter, the usable output power is slightly reduced as a result of filter losses. Generally no filter is required for narrowband amplifiers such as the backward wave amplifier or the klystron, because the bandwidth is less than the IF frequency and the image is adequately rejected.

Masers

The maser represents the ultimate in low noise characteristics, but requires complicated external circuitry, an external field, and operation at extremely low temperature (the temperature of liquid helium). (The term MASER is taken from the first letters of Microwave Amplification by Stimulated Emission of Radiation.) The operation of this device is based on the principles of quantum mechanics. "Bound" or planetary electrons within the atoms of any material possess a certain amount of energy, and the level of energy possessed by each electron is not constant. The energy level of an electron may be raised by causing the electron to absorb energy; it may be lowered by causing the electron to give up energy. Under normal conditions, with no external forces applied, the energy levels of the electrons within the material are distributed at random but with the higher-level electrons being more scarce than the lower-level ones.

Additional information concerning masers may be found in the February 1963 issue of the Digest of U.S. Naval Aviation Electronics, NavWeps 08-1-503.

Tunnel Diodes

Tunnel diodes may be used as input amplifiers where the noise can be tolerated in favor of simplicity. Although the noise factor is not so good as the maser of the parametric amplifier, it is lower than that of the triodes. The operating principles of tunnel diodes are discussed in Aviation Electronics Technician 3 & 2, NavPers 10317-C.

MIXERS

The purpose of the mixer in a superheterodyne receiver is to combine the frequency of the incoming signal with the frequency of the local oscillator, and to produce from these two a third frequency (the difference between them, usually) known as the INTERMEDIATE FREQUENCY (IF). The IF is normally much lower than either of the other two frequencies. The IF is amplified and used to carry the impressed intelligence of the incoming signal through the remainder of the RF circuits. If

10157

When cool colors are used to add distance and depth to a picture, it is known as aerial perspective.

VARYING ALL DIMENSIONS OF A COLOR

The three dimensions of color have been discussed separately in order to make them more easily understood. It remains a fact however, that when you mix colors, you will rarely change just one of the dimensions; you will usually alter the hue, value, and intensity simultaneously.

EFFECTS OF ONE COLOR ON ANOTHER

When you use colors in a painting, the hue and the intensity of each color are affected by the colors around it. When you first draw in a shadow tone on a piece of white paper, it often appears too dark because of the large expanse of white surrounding it, but, as you add more tones and build up the rest of the picture, the shadow area begins to look right. The same holds true of using colors. You must keep in mind the color of the object itself, the color of the light shining upon the object, and the color of any surface around the object which may reflect light back upon the object.

In figure 16-4, each of the letters in the top row were painted in true colors: red, yellow, blue and green, and were set under a white light. You will notice that each plane of the letters differs slightly from the others. The true colors of each letter can be seen best in the left vertical plane, where they are least affected by light or shadow.

In the second row, we have the same row of letters but under a warm yellow light. This has changed the colors in the top and left vertical planes. You can see that in the second row, the colors under the influence of yellow tend to appear warmer.

Figure 16-4.—Effect of one color on another.

10158

The bottom row of letters were all painted red, then each was placed on a different colored surface with a white light shining on it. On the right vertical plane, the shadow area is altered by the reflection from the colored surfaces. The red reflecting surface intensifies the red color in the shadow plane. The blue has created a violet tone in the shadow plane. The yellow has created an orange tone in the shadow plane. The shadow plane from the gray surface is neutral, and the light has not changed the hue of the shadow plane.

With each letter, the reflecting light has not affected either the top plane or the left vertical plane, they have remained the same throughout.

COLOR MIXING

As stated before, you will seldom use a color straight from the tube for a painting. Because of this, it will be of great importance to you that you acquire good color mixing habits from the beginning. Three important points to remember are: (1) always clean your brush before you pick up a color with it, (2) keep your mixtures simple, and (3) mix dark hues into lighter hues—for economy; it takes a small amount of blue into yellow to get the desired green hues. Large amounts of yellow are required when mixed with blue to obtain the desired green hue. With only two or three colors at a time, plus white and black, you can create almost any color you will ever need. If you mix more than two or three together, you will usually wind up with nothing but a muddy or dirty gray.

Some important facts to help you in your color mixing are:

(1) A series of intense orange hues may be formed by mixing vermilion red (intense red orange) with a warm yellow orange.

(2) A series of vivid yellow greens and greens may be formed by mixing turquoise blue (intense blue green) and a cool yellow.

(3) Rich violets may be formed by mixing a purplish red and an ultramarine blue (intense blue violet). The hues magenta (intense red), vermilion red, yellow, turquoise blue, ultramarine blue and purple are pure hues which are manufactured as such and are next to impossible to form through intermixing. Hues such as orange, green and violet (secondary hues), and yellow orange, yellow green and blue green (tertiary hues) are formed by mixing hues which lie adjacent to one another on the color wheel.

When a softness of hue rather than a sharp high intensity hue is desired, combining secondary hues accomplishes this best. For example, a mixture of orange and violet will result in a red of low value.

In the tertiary hue group, satisfactory results may be obtained by mixing green and violet to obtain a soft blue and by mixing orange and green to a dull yellow (olive or tannish cast).

SET PALETTE

When working in color, a prime problem for most beginners is the desire to put every pigment available on their palettes into the picture rather than taking advantage of the infinite number of color differences created by the variations of value and intensity.

Bright advancing colors normally serve their purpose best in small areas attracting attention or as accents. Several intense colors used in the same size areas compete with each other, and their effectiveness is canceled out.

A good way to overcome this problem and achieve color harmony and unity in your pictures is to use a set palette. A set palette is obtained by adding a small amount of any one color or a gray tone to all of the colors on your palette. You will find that the added color will have a greater effect on its complementary color than on the colors adjacent to it on the color wheel. Adding one color to all light areas and another color to all shadow areas is another way of obtaining variation. The added color may be warm or cool, depending upon the effect you are trying to achieve. When you want to emphasize one color in a picture, you should add a color to every other color on your palette except the color you want to emphasize.

Figure 16-5 shows how an illustrator with an arranged palette of colors will follow the same pattern throughout.

COLOR PSYCHOLOGY

It is known that color has a strong emotional effect on the viewer. By using selected colors carefully the illustrator can make the viewer feel cheerful or make him feel depressed. The viewer can be excited with one color or be soothed with another. You can fill the viewer with longing or make him feel at peace, just by the careful selection of colors. Because of this effect, you must learn to take advantage of these

10159

Figure 16-5.—Set palette.

effects in doing your work. The following suggested color interpretations are listed for your use:

Red . . . . . heat, anger, war, danger, excitement.

Yellow . . . . . sun, generates warmth without heat.

Blue . . . . . coolness, pleasure, space, hope, piety.

Green . . . . . springtime, summer foliage, safety, coolness, pleasant and restful.

Orange . . . . . warmth, autumn.

Purple . . . . . mystery, death, suspense, power, regalness. Should be rather restricted in use.

Cool colors . . . winter, early spring; dignified, formal.

Warm colors . . summer, fall, informal; friendly in nature.

You will find it necessary to apply your knowledge of color and how people are going to react to it in order to achieve the effect you are striving for.

CREATING EFFECTS THROUGH COLOR

Thus far in our study of color, we have discussed briefly the history of color, color organization, how a color effects other colors under different conditions, fundamental color mixing and the effect of colors on our emotions.

We will now discuss some of the techniques that, when understood, will greatly increase your ability to create interesting and dramatic works in color.

10160

LUSTROUS EFFECT

To accomplish a lustrous effect in color, the larger areas of the drawing must be composed of slightly shaded hues which are suppressed uniformly in value, and the smaller areas of the drawing are painted in pure hues. The suppressed colors will appear natural enough, although slightly on the dark side, as if seen in moderate illumination. When touches of pure intense colors are added, the pure colors will appear exceptionally brilliant in comparison with the suppressed colors. The added colors are said to be lustrous since they appear brighter than normal. The added paints do not have to be shiny; the effect is a visual illusion as in figure 16-6.

One method of creating a lustrous effect is to prepare a drawing with pure red, yellow, green or turquoise tempera paints on a white or gray background. Then, with an airbrush, coat the entire drawing with a uniform thin layer of black to reduce the intensity of the colors. Small touches of the original pure hues are then replaced on the drawing. These added touches will appear lustrous and shine forth with striking purity. They often appear to have a metallic sheen to them.

Figure 16-6.—Lustrous effect.

Another, and a more impressive method to achieve a lustrous effect, is to work in a dark background. With a selection of pure tempera colors, prepare a shade scale of three or four steps of value from purity to almost black for each basic hue. Vermilion red, oranges, yellow, vivid yellowish green and turquoise blue are best (avoid deep reds, blues and violet). Working the scale from the darker tones to the brighter and purer tones, paint a simple picture. The largest areas of the drawing should be in the deep tones. When the light pure tones are added to the foreground after the background is completely covered, the pure tones should appear extremely lustrous and far more brilliant than they actually are, as seen in figure 16-6.

The luster perceived by the viewer varies in type and each luster is visually unique. Luster may appear as translucent as a fine metallic cloth or the feathery edge of a silk scarf. Luster may also appear as bold and sharp as a solid polished metal with sharp highlights and shadows.

You do not paint lustrous surfaces realistically and you do not copy nature. The actual color value of a lustrous object is too bright to capture with a pigment. You have to contrast the purest hue of your value scale with the surroundings of the lustrous object by darkening the surrounding area until the effect appears realistic. For example, if you were to paint a red vase, you would not use a soft pink for a highlight since this would not achieve the lustrous effect, but would ruin it. The proper method would be to suppress the red or maroon color of the object and paint the highlight with a pure vermilion to achieve the greatest contrast. The highlight would then appear to shine brightly.

IRIDESCENT EFFECT

Iridescence is defined as a rainbow-like play of colors, such as is found in a soap bubble, in an opal, or in mother-of-pearl. To simulate the phenomenon of iridescence, our uniform suppression is in terms of a gray field in contrast to the blackish field we used in creating the lustrous effect.

10161

In nature, iridescence is an elusive quality. Iridescent colors in nature owe their existence to diffraction (bending of lightrays) rather than to the pigments inherent in the object. The surface of an iridescent object splits a ray of light into its components, and the viewer sees the various spectral hues separated from one another. The color of an iridescent object tends to change in value and hue when seen from different angles. This is a dynamic quality which seems to defy duplication in a static design such as a painting.

The effect of iridescence in a design is more subtle and softer than the effect of luster. Iridescence features the beauty of delicate tints and pastels against gray. The viewer will be given an illusion of mistiness as he views an iridescent effect. Incidental touches of pure hues or clean tints to this mistiness will take on a fascinating glint as it appears to shine as though endowed with an inherent luminosity; a quality which will seem quite separate from any characteristic of the paint itself.

Using tempera colors, prepare a series of medium valued tints (about halfway between purity and white) such as pink, peach, soft yellow, pale green, pale blue and lavender. Keep the tints as clear as possible, avoiding grayness or darkness. Paint a simple design confining the original tints to relatively small areas and imparting a gray cast to the larger areas. You may achieve the gray cast by adding neutral gray of lower value to the original colors, or by combining opposites. Adding neutral gray is the simplest method.

After completing the painting and the paper's surface is completely covered, (no white paper exposed) use an airbrush to apply a delicate coat of opaque pale gray over the entire surface until the painting appears misty. The final step is to replace touches of the original clean tints.

An alternate method for achieving an iridescent effect is to mix a series of clean tints. To these original clean tints, add equal amounts of a medium gray. Each of the original tints should have about three or four steps of graying from a clean tint to a neutral gray. Scale the color on the drawing gradually from the grayed tints into the clean tints, which should be placed as small touches, highlights or details. A general overall gray cast will establish and fix the illumination quality. This will, by comparison, lend unusual glory and iridescence to the minor areas occupied by the clean tints.

Figure 16-7.—Luminous effect.

18:01 10162

LUMINOUS EFFECT

A luminous object is an object which emits light or appears to have an inner glow (shining). The moon is said to be luminous although it is actually reflecting the sun's light. The effect of luminosity in a painting may be easily and effectively achieved through a carefully established arrangement of color tones and values. The viewer may be convincingly led to believe that light is being emitted from a painting's surface if the proper color tones and values are used throughout the painting, as shown in figure 16-7.

There are several methods for accenting the luminous quality of a hue. The simplest and the traditional methods are to surround the rich pure hue with dark values or with its opposite color on the color wheel. The result may prove disappointing if the color which is to appear luminous is lacking in purity.

There are several conditions which must be met before a color in a painting will provide the viewer with an illusion of the color's luminosity. They are:

1. The luminous area must be relatively small.
2. The color which is to appear luminous must be purer in chroma than its surroundings.
3. The color which is to appear luminous must be of a higher value than its surroundings.
4. The luminous hue must seem to prevail all of the other colors in the painting.
5. The other objects in the painting should appear soft and hazy as though the viewer's vision has been blurred by the relative brightness of the luminous object.

10163

CHAPTER 17

SHOP PROCEDURES AND PRODUCTION

SHOP PROCEDURES

In all graphic art departments, a large amount of time is spent on projects other than actual illustrating. They are essential projects and include the steps necessary for completing the job order. Such nonillustrative work ranges from simple picture mounting and mat cutting to the more complicated airbrush rendering, photo retouching, and the use of mechanical aids.

RUBBER CEMENT

A useful product which you will find yourself using more than any other is rubber cement. Of all the adhesives available, it is the most versatile, the easiest to handle, and the easiest to remove from almost any surface without leaving any mark.

Pieces that have been mounted with rubber cement can be adjusted or removed by applying rubber cement thinner along the edges of the piece. The thinner seeps beneath the edges and loosens the cement. Rubber cement and the cement thinner are highly flammable. Never use either near an open flame; don't use the thinner near a lighted cigarette. Rubber cement should be of the consistency of honey. The proper proportions, using a rubber cement dispenser jar, are two-thirds cement to one-third thinner. This proportions may vary with the user's preference.

A rubber cement pickup (a small triangular-shaped tool) is very useful in removing excess cement. It is rubbed gently over the dried cement and easily picks up the cement in hard to get at areas.

There are two methods of using rubber cement in mounting: the wet mount method and the dry mount method.

PHOTO AND ILLUSTRATION MOUNTING

Wet Mounting

When you use the wet mount method, the rubber cement is applied to only the underside of the piece being mounted. The first step is to cut the piece to the desired size with the desired margin. A sharp razor blade or x-acto knife is handy for this. On the mounting board, mark the exact position for the piece. Cover the reverse side of the piece being mounted evenly with cement and place it directly on the mounting board while wet. This enables the piece to be moved freely for proper alignment. When the piece is properly located, place a sheet of tissue paper over the piece and press the piece flat with a triangle. This squeezes out the excess cement which can then be removed.

Dry Mounting

The dry mount method is more often used when mounting photographs, type proofs, and artwork. Though not completely permanent, dry mounts hold extremely well. Both surfaces are covered evenly with cement and allowed to thoroughly dry. When dry, the two surfaces stick instantly upon contact. The first step in dry mounting is to secure the mounting board to your drawing board. Line up the piece being mounted with the desired margins marked, as in the wet process. Then apply cement to both surfaces and allow it to dry. When the cement is dry, place a sheet of tracing paper over the cemented mounting board leaving about one-quarter of an inch exposed at the top. This sheet prevents the sticking of the two cemented pieces. Position the piece being mounted and press it firmly against

the exposed area on the mounting board. Slowly withdraw the tracing paper as you gently smooth the piece against the mounting, working from the center outward. Repeat the process slowly until the piece is completely "stuck" down. Place a sheet of tissue over the work and draw the edge of a triangle over the work. Then remove the excess cement with a cement pickup.

Double Slip-Sheet Mounting

For mounting large pieces of art or drawings made on flimsy paper, the two slip-sheet method divides the work area and makes handling easier. Secure the mounting board to the drawing board and mark the corners as before to show margin. Coat both the mounting board and the underside of the art with cement and allow it to dry. When both pieces are completely dry, place two sheets of tracing paper over the mounting board, with the slip sheets overlapping slightly in the center. Place the art exactly within the corner marginal marks. Hold one half the art firmly with one hand as you gently withdraw the opposite slip sheet about half an inch. Smooth this strip down and continue the process with this slip-sheet until one-half the art is entirely cemented down. Then repeat the process with the remaining side. Smooth the art down and pick up the excess cement.

Dry Mounting Press

The dry mounting press offers clean fast mounting. A thin sheet of translucent material which dissolves under heat and adheres to and binds both surfaces is used for the adhesive. It is sometimes necessary that several sheets of adhesive be used for one job. The only restriction is that the sheets cannot overlap beneath the art; this will cause a seam to be visible. It is permissible to leave space between the sheets beneath the art. The dry mounting press is frequently used in graphic and photographic departments on photographs, photostats, or any paper lightweight enough for the heat to penetrate.

An electric "tacking iron" is used to fasten the work temporarily in place. The adhesive sheets are trimmed evenly with the photo. No adhesive should extend beyond the edge of the photo or it will stick to the press. A sheet of paper should be used to protect the photo when using the tacking iron. The photo is placed face up in the press with a protective tissue over it and heat and pressure are applied for 15 to 30 seconds. The tacking iron can be used to press down any bubbles.

CUTTING A MAT

It takes experience to cut a professional looking mat. The usual size mat is 3 x 4, meaning there are three unit margins at the top and sides and a four unit margin at the bottom. Quite often the work requires that a mat be cut for a picture that is only slightly too small for an existing frame. This necessitates that the above rule be set aside. Special matting board is available; and the tools needed for the job are a good

Figure 17-1.

straightedge, a ruler, a mat knife, and tape.

All measurements are made on the front side of the mat and tick marks are located at the corner points of the area to be cut. Before cutting, check the measurements against the desired area on the picture being matted so that any adjustments can be made before cutting.

Start the cut at any corner beginning at a tick mark. This is required to make clean, sharp corners. The knife can be held at an angle to make a beveled cut, or can be held at a right angle to the mat to make a square cut. Whichever you start, use the same cut all the way around, and do not extend the cut beyond the tick marks. An extra piece of mat board or cardboard beneath the mat makes cutting easier.

To attach the picture to the mat, attach a strip of tape to the back of the picture, allowing one-half of the tape to extend beyond the edge of the picture. Place the mat over the picture and, when it is lined up properly, press it against the protruding tape. This will hold the picture and the mat together while you turn them over and tape the remaining sides.

RESCALING

When you want to change the scale or size of a piece of artwork or layout without using any mechanical aids, you can do the job accurately and neatly with your T-square and triangle. Figure 17-1 illustrates how to scale up to a larger proportion. If you need to scale down, reverse the procedure shown in figure 17-1. The first step is to secure the art to the drawing board. Tape a large sheet of tracing paper over the art with the art in the upper left corner. Draw a diagonal line from the upper left corner to the lower right corner and extend the line beyond the corner as shown in figure 17-1. A horizontal and vertical line meeting anywhere on the diagonal will be correctly proportional. Figure 17-1 shows the art being doubled in size. The width of the art is doubled on the top horizontal line, then a vertical line is dropped to where it intersects with the diagonal. The bottom horizontal is drawn at this intersection.

If you want to relocate enlarged art on an enlarged rectangle, follow the procedure shown in figure 17-2. Extend the vertical and horizontal lines on the original until they meet the edge of the original rectangle. From the lower left corner, draw diagonal lines through the points as shown in figure 17-2 until they reach the edge of the larger rectangle. From the four new location points, draw vertical and horizontal lines; their intersection will locate the new area for the photo.

Figure 17-2.

you have not recently reviewed the basic principles of superheterodyne receivers in Basic Electronics, NavPers 10087-B, you should do so before continuing with this chapter.

The remaining pages of this chapter are devoted to some of the important considerations involved in the understanding of the operation of mixers. The first portion is a brief coverage of the local oscillator, followed by the triode mixer, the single-ended crystal mixer, and the balanced mixer. In some microwave equipments the mixer is used as the input circuit, while in others, the mixer is preceded by one or more stages of RF amplification at the frequency of the incoming signal.

INPUT SIGNALS

For operation of the mixer, it is necessary to provide two signals at slightly different frequencies. The first of these frequencies is the incoming signal, with its intelligence impressed upon it. This signal is picked up from the air in the form of electromagnetic waves, and is converted in the antenna circuits into electrical currents and voltages. From the antenna, this signal is carried to the mixer through some form of transmission line (usually coaxial cable or waveguide), possibly (but not necessarily) through an amplifier.

The second required frequency is produced by the local oscillator. The local oscillator may be a klystron, magnetron, backward wave oscillator, or any other type oscillator capable of producing a small amount of energy at the desired frequency. One type triode oscillator used at UHF frequencies is shown in figure 12-32.

The local oscillator, shown at the right in figure 12-32 (A), is similar in construction to the RF amplifier except that the grid cylinder is partly cut away near the local oscillator tube. Thus C_{pk} in the oscillator equivalent circuit (B) includes both the plate to cathode capacitance of the tube and the external coupling capacitance resulting from the opening in the grid line. All cylinders of the oscillator, tuner, like those of the RF amplifier, operate at ground voltage, and the cathode is maintained at a positive potential with respect to ground because of the bias voltage developed across C_{k2} in parallel with R_{k2}.

The local oscillator is tuned in accordance with the principles discussed for the lighthouse tube oscillator in an early part of this chapter. The plate line length is the primary control for frequency and, in fact, constitutes the main tuning control for the receiver. Tuning is accomplished by means of a knob or dial connected to the plate line shorting plunger through a mechanism not shown in the figure. The cathode line length governs the magnitude and phase of the voltage fed back to the cathode circuit from the plate circuit and must be adjusted so that a capacitive reactance appears between grid and cathode at the oscillation frequency. At frequencies in the neighborhood of 1,000 megacycles per second, it is mechanically feasible to choose line lengths so that each line employs its lowest mode of resonance. Thus the cathode line is approximately one-quarter wave at the oscillator frequency, and the plate line is less than a quarter wave.

TRIODE MIXERS

Power coupled from the plate line of the local oscillator is applied, together with input signals from the RF amplifier, to the cathode line of the mixer tube V3. A component of current at a frequency equal to the difference between the local oscillator and signal frequencies is produced in the plate circuit of the mixer, and the plate circuit is tuned to this difference frequency.

The mixer tuner differs from the local oscillator and RF amplifier tuners in that it employs a coaxial line cavity only between cathode and grid, lumped parameters being used in the plate circuit. The tuned plate circuit consists of inductor L_{p3} in parallel with interelectrode capacitance C_{gp}, the series combination of C_c and the input resistance R_c of the output line, and the variable capacitance C4 formed by a movable metallic disk near the plate terminal of the tube. The capacitance of C4 is varied by changing the disk position by means of a rod which passes through the end of the tuner.

The various components comprising the tuned plate load of the mixer are illustrated in figure 12-32 (B). Because input signals are applied between grid and cathode of the mixer and the intermediate frequency signals appear between grid and plate, the equivalent circuit is represented as a grid return circuit. From the equivalent circuit it may be seen that the variable capacitor C4 serves to tune the remaining plate circuit elements to resonance at the intermediate frequency. Placing capacitor C_c in

1014

THE PANTOGRAPH

The pantograph is a mechanical instrument used to enlarge or reduce or copy a drawing or photograph. It consists of four arms, of either wood or metal, joined at four points. Secure point A (fig. 17-3) to the drawing board. Set trace point C over the object to be copied. Point F, a pencil point, repeats the motions of point C and copies the object on the drawing paper. To adjust the degree of enlargement or reduction, move the connecting points B and E along a scale marked on the arms. Watch point C, following the lines of the original, as you guide the pencil at point F with your hand.

THE AIRBRUSH

In illustrative artwork, airbrush art can be broken down into various specific applications. Airbrush rendering and airbrush photo retouching may be considered the two major categories. An airbrush painting is done on drawing paper or illustration board. It may be pictorial, abstract, or mechanical insofar as subject matter is concerned. It may be partially or completely done with the airbrush, using water color paints or dyes. Photo retouching involves the application of water colors — generally opaque grays — to photographs. Minor adjustments may be made on the photograph or the photographic image may be covered entirely by painting over it with the airbrush. Retouching may be done either in black and white or in full color.

Sources of Air Supply

An air compressor is usually used with an airbrush, although metal cylinders of any safe gas can be used when an air compressor is not available. The air supply is connected to the airbrush by means of a rubber hose, and a regulator on the compressor or gas container enables the user to adjust the pressure to the proper working level, which is about 25 pounds.

Airbrushes

Several manufacturers make airbrushes of various types and models. The two basic types used by illustrators are the "single action" type and the "double action" type. With the single action airbrush the paint flow is obtained by one action: pressing down on the finger lever. This design is the simplest with the least number of parts. A color adjuster can be regulated for fine or coarse effect, but the spray pattern cannot be varied during a stroke, except by varying the distance from the paper. While good for background work and simple airbrush art, this model does not permit the precise control attainable with the double action brush.

Figure 17-3.

The spray pattern from the double action airbrush is controlled by two actions: pressing down on the finger lever and pulling back on the finger lever — the further back, the larger the pattern. This allows for easier control and variation of the pattern. There are three major all-around studio brushes of the double action type, and a more specialized airbrush for the very finest detail work in photo retouching and air painting, giving the illustrator absolute color control and enabling him to draw in a freehand manner with pencil accuracy a wide range of patterns.

Pigments

Any finely ground water soluble pigment, alcohol color, or aniline dye can be used in the airbrush. These can be either transparent or opaque color. Opaque grays are used for retouching and rendering. The Grumbacher Gamma grays, scaled in six values of neutral gray, reproduce as they actually appear to the eye. Other retouch grays are made in warm (brownish) tones and cool (bluish) tones for retouching photos.

Paper

A good grade of paper or illustration board is required for airbrush, especially finished artwork. The Grumbacher illustration board, and 3-ply bristol board are excellent for finished work. For practice, the 1-ply kid-finish or heavy drawing paper is satisfactory.

10165

Other Materials

Areas not to be sprayed are covered with masks made of drawing paper, stencil paper or acetate. Intricate areas are managed by attaching frisket paper to the drawing with rubber cement, and cutting out the areas to be airbrushed. A frisket knife is used for the cutting. A rubber cement dispenser, palette, red sable brushes and the usual drawing instruments complete the list of supplies.

Maintenance

For proper care and maintenance, and operating principles of a particular type airbrush, reference should be made to the manufacturer's instruction book. The manufacturer's instruction book will also enable you to properly clean your airbrush, determine causes of breakdown, and make minor replacements and adjustments.

Figure 17-4.

OPERATING THE AIRBRUSH

Start by diluting the pigment to approximately the consistency used to secure a medium value wash, remove it from the palette with a bristle brush or eye dropper and fill the color-cup with it. See figure 17-4. Do not use a brush that will shed hairs, as they will get into the airbrush and clog it. To hold the brush, wrap the hose around your right wrist. When you hold the brush this way, the hose will be restrained by your wrist and will not flop over the paper.

Figure 17-5.

Position yourself so that you are sitting upright, but comfortably relaxed, with enough room between your arm and the drawing so that your arm can move freely. Hold the brush about 8 inches above and at a right angle to the paper through the entire operation. To airpaint properly, three distinct motions must be controlled and coordinated. First, set the hand in motion; second, press the finger lever down, releasing air but not paint; third, release the paint by gently pulling back the finger lever. See figure 17-5. During these three operations, keep your hand in motion to the end of the stroke. At the end of the stroke, allow the finger lever to move forward, stopping the paint, then up, stopping the air flow.

It is very important that the three actions be separate, but follow each other closely. Running the first and second actions together will result in a sudden burst of paint at the beginning of the next stroke. The entire movement should be slow and steady. The whole arm moves across the paper from the shoulder; do not dip the hand or turn the wrist, or change the angle of the brush.

10166

Flat Wash

Prepare a simple paper mask as shown in figure 17-6. Tape the mask to the drawing paper with masking tape, allowing the tape to overlap the paper by about an eighth of an inch. Press the tape firmly against the paper to prevent any paint from seeping underneath.

Following the procedure just explained, airpaint a tone across the top of the drawing paper. Avoid a light streak across the top of the sheet by allowing the spray pattern to overlap the top strip of masking tape.

With your hand in motion, start at the top left outside of the mask and pull back on the finger lever while still over the mask. This allows the full strength of the pattern to fall on the exposed portion of the paper. The finger lever must remain pulled back until the opposite side of the page has been reached. Now return to the left edge, allowing the second stroke to overlap the first, being careful that no streak will show from the overlap. See figure 17-7.

Continue down the page, allowing the last stroke to overlap the bottom strip of masking tape. This first coverage should be kept light in value, and darkened by repeating the entire process as many times as necessary to create the value desired.

Be certain that the drawing paper and the masking tape are dry before removing the mask. To avoid any damage to the surface of the drawing paper, remove the tape slowly and carefully.

Satisfactory results may not appear right away, for control of the airbrush is a matter of practice.

Graded Wash

Prepare a sheet of drawing paper with a mask as before. Start the spray pattern at the bottom of the page, since this will be the darkest area. Proceed as you did with the first strokes of the flat wash, except that as you progress from the bottom you allow the paint to fade off completely before you reach the top of the exposed area of the drawing paper. See figure 17-8.

Next, start again at the bottom. Proceed upward as before, except that instead of following the pattern up as far as the first passage, stop just short of it, allowing the tone to fade out. It will be necessary to repeat this procedure several times, stopping short of each of the previous passages each time. It may be necessary to add a little more pigment to the solution for the last few passages at the bottom since the paint is very diluted for the gray tone. In figure 17-9 you can see that the top of the drawing is white, the bottom is black, and there is a smooth, graded transition between.

Spotlight Effect

To create a spotlight effect, cut a paper mask with a square opening. Tape the mask over a sheet of clean drawing paper so that it will not shift.

Turn one corner toward you and airpaint horizontally across the corner two or three times, aiming the pattern so that most of the paint spray falls on the mask at this corner. See figure 17-10.

Without moving your aim, bend your wrist upward so the spray pattern is raised slightly.

Return to the original position and apply about two more strokes in the corner again. Now rotate the paper, taking each corner in turn, and repeat the above procedure in the same manner.

With the four corners sprayed in, airpaint about a half-inch of each corner in solid black, fading gradually into the light area. Until the black is added, keep all of the corners light. After all corners have been painted, join them with a light tone along the edge of the mask. Remove the mask as before.

There should be a smooth transition with the spotlight fairly white and about one half-inch of solid black at each corner as shown in figure 17-11.

MAKING A FRISKET

Areas which are not to be sprayed when airbrushing are protected by means of a mask or frisket. A frisket is a sheet of frisket paper coated with rubber cement. It is placed over the drawing or photo and cut out to expose the areas to be painted.

First coat either side of the frisket paper with a thin even coat of thinned rubber cement. Allow it to dry, then give it a second coat. Care must be taken not to lift off the dried first coating.

When the second coat is dry, lift the frisket and turn it over so that the coated surface is face down and place it slowly over the drawing, allowing the middle of the paper to contact the drawing paper first.

Carefully flatten the frisket working from the center outward with the hand or a flat edge.

10167

Figure 17-6.

Figure 17-7.

Figure 17-8.

Figure 17-9.

Figure 17-10.

Figure 17-11.

10168

With a frisket knife, cut out the area to be exposed. Use a straightedge where straight lines are wanted. Be careful to cut only through the frisket paper and not into the drawing.

Carefully lift one corner of the frisket paper and remove the frisket from the paper. With a rubber cement pickup, remove any rubber cement that has remained on the open area, being extremely careful along the cut edges of the frisket.

Now the exposed area is ready for airpainting.

When the area has been airpainted, and both paint and frisket are dry, remove the frisket. Using the rubber cement pickup, remove any cement on the paper. Other friskets may be used over the airbrushed area when further work is necessary.

RENDERING THE BASIC FORMS

When rendering the basic forms with the airbrush, you will want to obtain the same three dimensional character of these forms as you did in chapter 11.

In creating your light source to shadow the basic forms, a single light from the upper left at a 45-degree angle may be assumed, although in real practice, a light source from an angle other than this may be needed to correctly present the illustration.

Figure 17-12.

The Cylinder

The first step in making a cylinder form is to outline a cylinder as it will look; that is, a rectangle. Place a frisket over it and cut the frisket along the outline. Remove the inner frisket and clean the working area of the paper of any rubber cement which may have remained from the frisket.

In this exercise, leave a reflected light at the bottom of the cylinder, and have the shading start with a soft edge. To do this, use a raised blotter as a mask. See figure 17-12. For the first few strokes, work almost vertically and turn the brush slightly upward to fade the tone gradually out. Do not spray too long or get this area too dark, but have this area unfinished.

Now, turning the drawing paper upside down, start at the top of the shadow and do as you did in the previous step, except this time make the reflected light narrower. To do this, do not cover as much of the cylinder as you did in the previous step. Do most of this shadow with the brush held close and in a vertical position. Now, without the blotter, airpaint the bottom shadow until a very black area forms across the lower edge of the bottom shadow. It will be necessary to work close so that you do not soften the bottom of the shadow too much. See figire 17-13.

In figure 17-13, the really black area is only at the bottom of the bottom shadow and it fades out gradually to a white highlight about one-third the way down from the top. The shadow at the top is narrower and lighter and the reflected light at the top is narrower and lighter than the reflected light at the bottom.

The Cube

In rendering a cube, draw a dark sharp outline of the cube. Place a frisket over the paper, leaving wide borders of frisket all around. For

Figure 17-16.

Figure 17-17.

this exercise, start with the darkest plane so it will serve as a value guide for the other planes and will save masking off certain areas when progressing from dark to light planes.

Turn the drawing so that the corner to eventually become the darkest is nearest to you and remove the frisket from this plane. Apply pigment to this corner, fading it out to the corner which is diagonally opposite it. See figure 17-14. Start each passage in the darkest corner, so that it receives most of the pigment. The darkest tone should not be reached until the end of this exercise.

Now remove the frisket from the middle plane. Airpaint on the diagnonal as before, keeping as close as possible to corner No. 1 because it is desirable to have as much contrast as possible between the intersection point of the three planes. Corner No. 2 should not be quite as dark as the black in the first plane. It is not necessary that the first plane be covered with frisket paper. See figure 17-15.

Remove the frisket from the last plane. Airpaint a graded wash that is still lighter than that used on the second plane. No pigment is applied to the far corner, so that it will remain white as shown in figure 17-16. The frisket is now removed from the area surrounding the drawing, and any rubber cement left on the paper removed with a rubber cement pickup. Note that with the frisket removed all of the planes are smoothly graded in value. The only black is in the top left corner of the darkest plane, and the only white is next to it, with the third corner of a value halfway between the two. The completed cube is shown right side up in figure 17-17. In figures 17-14, 15, and 16, the cube was shown at the angle from which you would view it while doing the work.

The Sphere

To render a sphere draw a circle and prepare the drawing paper as before by removing the frisket from the working area and cleaning the working area of any rubber cement which may have stuck to it.

Airpaint a very light tone around the edge of the sphere, allowing the spray to fall on the frisket. Do this with short strokes in both directions since long strokes here are difficult to control. Keep the tone as even as possible, fading it out gradually on the inside edge.

1376 10170

147

Figure 17-18.

Figure 17-19.

Figure 17-20.

Carry this coverage up farther from the bottom, leaving the highlight—a small circular area at the upper left of the spere. The highlight should be left as white as possible. See figure 17-18.

In the lower right area, airpaint a shadow along the right side a short distance from the frisket, then paint across the bottom and up the left side as shown in figure 17-19.

Now begin your heavy shading, leaving a reflected light. The shading (as in the previous exercise) should be of short strokes in all directions except when fading out either at the upper right or upper left; work here in only one direction.

At the top of the sphere, airpaint a slightly dark tone off the edge of the frisket, then return to the lower right shadow and continue to darken this area. Now work on the solid black tone, which is airpainted in the approximate shape of a crescent. Full black is limited to this area. See figure 17-20.

Remove the frisket and the sphere is finished. The reflected light extends about two-thirds of the way around the sphere. The highlight is in the upper left area and the darkest area is diagonally opposite it in the lower right area. The only solid black should be the crescent shape in this area; the tone fades gradually and smoothly to the highlight. Always pull the finger lever back only slightly and build the tones up gradually.

PHOTOGRAPHS

Photographs are rarely used as illustrations without some work being done on them. This work can range from simple silhouetting or cropping to the more precise retouching. Photographs must be handled with care because the surface is extremely delicate. Most photographs are retouched to either bring out important features or suppress undesirable features. It may be necessary sometimes to eliminate unnecessary features completely.

The surface of a glossy photograph usually has a light film of oil on it which is resistant to water color. This film is easily removed by carefully rubbing the surface with fuller's earth (a fine white powder).

Photographs are not alike in tonal values. Some may be warm while others are cool. For cool tonal values, a cool gray can be made by mixing lampblack and opaque white. To make a warm gray, a touch of yellow ochre is added to the lampblack and opaque white mixture.

When retouching is apparent in the reproduction, it will lose its natural believability and look fixed-up. Care must be exercised never to over-retouch.

Whenever opaque white is used it must be a pure white or it will reproduce as a light gray.

10171

Figure 17-21.

Silhouetting

When a portion of a photograph is to be reproduced without the background, the desired object is outlined with white opaque. The first steps are to mount the photo, rub the surface with fuller's earth, and blow away the residue. The opaque white should very slightly overlap the object being silhouetted. It is not necessary to white out the entire background. A line about 1/4 to 3/8 inches wide around the object is sufficient. When printed, it will be reproduced with the complete elimination of the original background. Figure 17-21 shows silhouetting.

Cropping

Crop marks are directions to the platemakers indicating how much of the photo is to be used. Cropping is done to eliminate meaningless details and to focus interest on the important features of the picture. Since the corners of photographs are rarely square, it is a good habit to establish a squared-up figure inside the original edges. Cut two right angles from heavy white bond. Place these over the photograph and move them about freely until good composition and proportion are obtained. Mark the corners with grease pencil (which is easily removed later with a soft tissue). Remove the two paper right angles and mark the mounting board, not the photograph, where the photo is to be cropped. Figure 17-22 shows this procedure.

Removing Spots from Photographs

Sometimes a photograph will contain spots or scratches which must be corrected before they can be reproduced. This is done with a watercolor sable brush, opaque white and lampblack. A series of grays is mixed so that the tone value of the photograph is matched exactly by the paint in order that the retouching will not show. The photograph is first wiped with the fuller's earth. The tones for the light areas are mixed first and the flaws on the photo are painted over. The darker tones are mixed and the flaws in the dark areas are corrected. Avoid making fingerpints around the areas to be painted. The skin will leave an oily film which prevents the paint from adhering to the photo's surface. Small spots can be eliminated by using a Stabels or similar pencil which is made especially for photo retouching. A slow fine circular motion is used to match the gray tones. Care must be exercised to avoid digging into the pictures surface.

Removing an Object from the Photograph

It is sometimes necessary to completely remove an object from a photograph before it is suitable for reproduction. If the background is a simple flat tone, the airbrush can be used, but if the background contains details and textures, the brush and opaque paints are necessary. The same procedure is used when removing spots. The light tones are painted first, then the middle tones are

10172

Figure 17-22.

mixed and painted in with the dark tones held for last. Details and textures are matched using the different techniques necessary to match the textures in the photograph as shown in figure 17-23.

Removing or Softening the Background

It is sometimes necessary to remove or soften distracting backgrounds. Sometimes only a particular object will need to be removed and the rest of the background toned down. It may be more appropriate to replace the entire background with a gray tone. To do this; the subject is silhouetted as described before, and the platemaker is instructed to fill in a gray tone over the background. Another method is to apply a frisket to the area to be retained and using the airbrush apply an even coat of gray, either light or dark, whichever is needed, over the undesired area. After removing the frisket, any excess paint which may have seeped underneath may be wiped off the subject with small wads of moist cotton that have been twisted onto the end of a brush handle (fig. 17-24). The edges of the subject may need to be retouched to avoid the subject's edges from being too sharp and unnatural.

Figure 17-23.—Removal of objects by retouching.

Figure 17-24.

10173

series with the output cable isolates the cable from the power supply voltage and causes the low input impedance R_c of the cable to appear as a higher resistance across the entire circuit.

The receiver input circuit of figure 12-32 (A) requires that the interconnecting cable between RF amplifier and mixer be short. Otherwise appreciable attenuation of received signals will occur in the cable and cause noise generated in the mixer to become important. If cable loss is excessive, it may become necessary to employ a second stage of RF amplification in order to maintain the signal level well above the noise level of the mixer.

SINGLE-ENDED CRYSTAL MIXERS

Because crystals are delicate, they must be protected extremely well by the TR device in order to avoid burnout during transmission. Vacuum tubes, on the other hand, are able to withstand relatively large amounts of transmitter power. Mixer circuits employing triodes have a somewhat higher conversion gain than crystal mixers, although they generate more noise. The effect of the increased noise may be offset at ultrahigh frequencies by preceding the triode mixer by one or more stages of radiofrequency amplification—the noise figure of a triode is appreciably less when used as an amplifier than when used as a mixer.

Unfortunately, most tubes that are available for operation in the microwave region generate an excessive amount of noise and are therefore not suitable for the input circuits of microwave receivers. Consequently, use of vacuum tube input circuits is usually restricted to receivers that operate in and below the UHF range.

Echo signals of a microwave radar system, after passing through the TR device, are applied to the crystal mixer. A voltage from a local oscillator is applied to the mixer simultaneously with the echo signals, and signals at the intermediate frequency are derived at the mixer output terminals.

The important features of a 10-cm mixer employing coaxial line sections are given in figure 12-33 (A).

Echo signals are coupled into the transmission line section between TR cavity and crystal by means of a coupling loop which penetrates a short distance into the cavity. The crystal fits snugly into the inner conductor of the line and is held concentric with the outer conductor by means of a dielectric bead. The local oscillator signal is introduced into the mixer assembly by means of a coupling probe located approximately a quarter wave (at the local oscillator frequency) from the coupling loop in the TR cavity. A high impedance in the direction of the cavity is thus presented to the local oscillator signal at the probe. The strength of the local oscillator signal at the crystal may be changed by varying the distance the probe extends into the main line. Power from the local oscillator is conducted to the probe via a section of transmission line.

Connection between the crystal and inner conductor of the line section carrying IF signals is provided by a spring contact (fig. 12-33 (A)). The half-wave RF choke appearing on the IF side of the crystal provides an electrical short circuit for radio frequency signals at point B. The d-c return path required for crystal current is provided at the RF end of the mixer assembly by the TR coupling loop and at the IF end by the shunt inductance element located in the grid circuit of the input IF amplifier stage.

A two-wire equivalent circuit of the mixer is given in figure 12-33 (B). If small losses in the RF line and TR cavity are ignored, the portion of the RF transmission system between antenna and output terminals of the TR cavity may be represented by a signal current source I_s in shunt with the characteristic resistance R_c of the transmission line. Because the local oscillator is loosely coupled to the main line, negligible admittance appears in shunt with the lines A and B in figure 12-33 (B). Elements L1 and C1 represent the RF choke at the IF end of the crystal and are series resonant at the echo signal frequency. Hence line B is terminated by the crystal at the echo signal frequency. For maximum receiver sensitivity it is important that essentially all the echo power available at the TR device be transferred to the crystal. The crystal should therefore present a matched load termination to the main line section. Fortunately 10-cm crystal units, when operated with 5/16-inch 50-ohm coaxial lines, provide essentially a matched RF load for the line. An impedance changing device between crystal and TR cavity is therefore unnecessary.

Because the local oscillator is loosely coupled to the main line containing the crystal, an appreciable mismatch of impedance exists on the local oscillator line at the coupling probe. A large impedance mismatch is in general undesirable because of the wide variations in local

1015

COMPOSITE PHOTOS

A composite photo is a picture that is composed of parts of two or more photographs. All of the photos used must be of the same scale so that the inserted objects will fit proportionally in the larger photo as shown in figure 17-25.

First the objects to be inserted are undercut at about a 45 degree angle. The back of the cutouts must be carefully sanded with very fine sandpaper until the thickness of the paper is gone. Rubber cement is applied to the background photo and the insert is glued down and the excess cement removed.

The composite is retouched with necessary shadows added and any spots removed. Making a composite is the only answer when you need the subject with a particular background and it isn't possible to have the subject photographed with the background.

Figure 17-25.

MECHANICAL AIDS IN ILLUSTRATING

There are several mechanical aids available which help to cut down plate cost and allow accurate, foolproof reproduction of black and white drawings.

CRAFTINT

Craftint is a convenient product with which you add tones to a line drawing and still having the drawing reproduced as a line plate. Craftint papers come in single or double tone in a variety of screen patterns. The pencil drawing is done on the craftint paper, then the black areas are put in with pen or brush and waterproof India ink. Fingerprints repel the developing solution so a slip sheet must be kept beneath the hand. The dark tone developer is applied to the areas where a dark tone is desired. Enough developer is applied to bring up sharp, even tones, but all excess developer must be blotted up right away.

After all of the dark areas desired are developed the light tone developer is applied where light grays are desired. After the surface is dry, pencil lines are erased and any black and white accents desired may be added.

ZIP-A-TONE

The Zip-A-Tone sheet is a transparent sheet covered with minute dots or lines. It is applied over a drawing, the areas where the tonal effect is not desired are cut away. There are many patterns and screens available. The pattern to be used depends on the effect you want and the amount of reduction that may take place in the reproduction stages. First, a drawing is made

10174

Figure 17-26.

with a brush or pen. All pencil lines must be removed and all corrections made before the Zip-A-Tone sheet is applied. The Zip-A-Tone is burnished to the drawing and then a razor blade or frisket knife is used to remove the Zip-A-Tone from the areas where the screen is not wanted. See figure 17-26.

SHOP PRODUCTION

The preparation of printing plates varies according to the method of reproduction to be used; but in both letterpress and offset printing the general procedure can be simplified something like this: (1) Camera stage; All artwork, line and tonal, is photographed onto negatives to the exact size it is to be printed. (2) Stripping; All negatives prepared in step 1 are stripped together according to the layout provided to the stripper. (3) Opaqueing; With brush and opaque paint, the platemaker "opaques" areas on the negatives that should not appear on the finished plate. In offset lithography, a blueprint or brown print called a vandyke is made for checking by a

10175

Figure 17-27.

production man. (4) Plate making; The negative is placed on a sensitized metal plate and exposed to light. The plate is then developed. (5) Proving; A proof is pulled when the letterpress is used. The offset uses the blueprint or vandyke as explained.

LETTERPRESS

With the letterpress process, the line and tonal art are usually plated separately. The plates are etched deeply so that the surface that will print is raised. Type is often combined with these plates and both are "locked up" together into one "form" for printing. Printing ink is transferred from the raised surface of this form directly to the paper. A screen must be specified when ordering a halftone plate. Fine screen halftones must be printed on glossy paper for best results. The plate is mounted on a wooden block. Figure 17-27 shows the simplified steps necessary for letterpress reproduction.

OFFSET

The camera stage of the offset process is almost identical to the camera stage of the letterpress process. The work is photographed and everything, tonal, line elements, and type, are transferred to a thin metal plate. With offset, the inked impression is transferred or offset from the plate to a rubber blanket and then to the paper. The word offset derives from this process of offsetting the image from the plate to the rubber blanket before it contacts the paper. Halftones in offset print are very good on almost

10176

Figure 17-28.

any paper—even very rough textured stock. Figure 17-28 shows the simplified steps necessary for offset reproduction.

LINE REPRODUCTION

A photo-engraver is the one who makes the plates for letterpress printing and the plates are called photo-engravings or engravings. The simplest engraving is a line plate or line cut. Line plates are usually made of zinc and are blocked; that is, attached to a hardwood base exactly type high (0.918 inch). Line cuts are printed on almost any type of paper; they are especially adaptable to coarse newsprint paper. A line plate is made from art work containing only lines and areas of solid color (usually black) and white. Line art is usually done in pen or brush and ink. Line work to be reproduced in line must not contain any gray or tonal areas, simply black and white. A negative of the work is made and the images are then reversed. When the plate is made, the clear portions of the negative, which are the actual printing areas on the plate, allow the light to pass through and hit the sensitized metal. When the plate is passed through the acid baths of the developing process, the acid will etch or eat away those areas that were not exposed to the light. The areas etched away will be the white, clear areas on the print.

HALFTONE REPRODUCTION

All that the engraver cannot shoot as line must be shot as halftone. A haltone engraving is usually made of copper. Almost any tonal subject can be reproduced with the process.

10177

Figure 17-29.

The halftone process is accomplished by photographing the material through a halftone screen. The halftone or engravers screen consists of two glass plates that are covered with very fine parallel lines. The two plates are cemented together so that the lines of one plate cross the lines of the second plate at right angles. The screen is placed in the camera directly in front of the film. Light strikes the screen when the exposure is made and the screen breaks the tonal image into thousands of very small dots on the negative film. Except for the screen, the same process is used in making a halftone plate as in making a line plate. The very small black dots on a finished halftone engraving are in effect a miniature line cut. Where the drawing was light, black dots on the corresponding section of the plate are small. Where the art is dark, the dots are large. The eye, at the proper distance from the reproduction blends these dots into tones which range from white through gray to black.

Figure 17-29 shows a halftone reproduction and an enlargement of a section of the reproduction. You will notice that the halftone is a refined line cut.

SILK SCREEN PRINTING

Printing by means of cutout paper or metal stencils has long been a fast, easy means of lettering signs and applying decorations. The letters and designs made with a stencil show undesirable unpainted areas caused by bridges or ties which hold islands of the stencil in place. Silk screen printing is a method devised to eliminate these undesirable bridges or ties. It has developed in the past 50 years from a crude, seldom used method to an accepted method.

Silk screen printing can be used for producing posters, display cards, and various other items often required at a Navy activity. It is versatile in its effects, which range from the transparent appearance of water colors to the heavy impasto of oil paints.

Basic equipment includes a sheet of silk, a frame, a squeegee, paint, and material for making a stencil.

PRINTING FRAME

Commercially manufactured frames are available, or a frame similar to the one shown in figure 17-30 can be made locally. The size of the frame will limit the size of the prints which can be made. The inside of the screen frame should be long enough to provide reservoir space at both ends for the paint. The frame should be made to accommodate standard sizes of paper. It may be as small as a postcard or as large as 4 feet by 5 feet.

SCREEN

The most satisfactory screen material is pure silk. Number 8xx (86 meshes to the inch) or number 10xx (110 meshes to the inch) silk is satisfactory for all paper and film stenciling.

10178

Figure 17-30.

The silk is stretched on the frame by fastening it in the middle at both sides and ends, and gradually working toward the corners. The threads in the silk should be placed parallel to the sides and ends of the frame. Organdy may be used in place of silk because it is less expensive; but it will stretch and sag under use, so that accurate register of colors is difficult to obtain.

STENCIL

With the screen stretched on the frame, you could pour paint into the frame and draw the squeegee across the screen to paint a solid color on a white card. A simple way to make a stencil is to place a sheet of stencil paper on the baseboard and cut out the desired design. Leave all pieces of the stencil in place on the baseboard, lower the frame, and spread the paint across the screen. The paint will stick the entire stencil to the screen when the frame is raised. The pieces of the stencil covering the areas to be painted must be peeled off the screen with tweezers and the stencil is complete. When the frame is lowered again and the squeegee is drawn across the screen, the paper prevents the passage of paint so that a white design is left unpainted.

The stencil paper method of preparing a stencil is one of several ways to make a stencil and should be used only when a limited number of prints is desired. For making larger quantities of prints, the paper stencil can be adhered to the screen with shellac and a warm flat iron. A prepared film material with a translucent (glassine paper) backing and a thin coating of lacquer is probably the most popular method of preparing stencils. The lacquer is cut and peeled off the backing in areas which are to be printed. The remaining lacquer film is then adhered to the silk screen. Stencils may also be prepared by using lacquer (with or without sizing), glue, shellac, tusche and glue, or with a light sensitized gelatine film (photographically). Each of these methods has some advantages and each method should be tried before it is rejected.

PAINTS

The process paints available for silk screen printing may be either oil paints or water colors. The oil paints are made from finely ground pigments mixed in an oil-base vehicle. Water colors have the pigments mixed in glycerine in a gum-base. Silk screen process paints are prepared by the manufacturer in the proper working consistency and packaged in various sized containers. A large selection of colors are available, and additional shades or tones can be produced by mixing.

THE SQUEEGEE

The paint is spread and forced through the screen with a squeegee. The squeegee as shown in figure 17-31 is similar to the windshield wiper blade of a car, but much larger. The

Figure 17-31.

10179

wooden holder has a groove for holding the blade. The blade may be either rubber or neoprene (synthetic rubber). Neoprene will last longer than rubber because the oils in the paint tend to soften rubber.

The squeegee should be short enough to fit between the side members of the frame and long enough to cover the widest part of the stencil. A nail driven in each of the wooden holder as shown in figure 17-31 will help to keep the holder clean by preventing it from falling into the paint.

The blade should be square on the botton. For best results, the blade should be held at about a 60-degree angle when pushing the paint from one end of the frame to the other. Practice will help you determine the angle to use to obtain the best impression.

PRINTING

A print is made each time the paint is moved from one end of the frame to the other. As prints are made, they must be stored in some way to prevent them from sticking together or smearing while they are drying. Specially designed storage racks will accommodate several prints in a comparatively small space.

After the desired number of prints have been made, all paint must be cleaned from the screen, the frame, and the squeegee. Always be sure to destroy all oily or paint-soaked cleaning rags in an incinerator. If this is not possible, place them in an approved metal container to prevent spontaneous combustion.

10180

CHAPTER 18

CARTOONING

What is a cartoon ?

Webster defines a cartoon as (1) "An artist's full-size design or study, to be transferred or copied, as in making fresco paintings, stained-glass windows, etc., (2) A large pictorial sketch; esp., a pictorial caricature." Another definition is the one stated by Lawrence Larian in his book Cartooning for Everybody: "A cartoon is a funny picture, any picture that's drawn to make people laugh." Funny or humorous drawings are considered by many illustrators to be the most effective form of illustrative communication because of the way they attract a person's attention. Attention-getting is a prime factor in drawing cartoons.

What makes a humorous cartoon readily acceptable is that most people are able to laugh at their own awkwardness and shortcomings. Also, man has the ability to identify himself with other creatures and still remain a man. An example of the latter is to create the likeness of a bird to represent a pilot since both are fliers. Even with man's gift of humor, it is easy to offend or create undersirable ractions. Because of this, you must remember that the object of your cartoon is to create interest and appreciation by all, especially by those whom the cartoon may characterize. There are exceptions to this rule (for example, political cartoons), but as a military illustrator you will be doing this type of cartooning. Your job is to follow the rules of good taste in cartooning as you have done in your illustrations.

What are you as a cartoonist? You are a story teller with a sense of humor, telling a story in pictures. The stories are short and should be told easily and suddenly. The cartoon should give the impression of being natural and spontaneous.

Cartoons are usually drawn in a simple, unsophisticated style, lacking in detail, but emphasizing the actions and attitudes of the characters.

Figure 18-1.

10181

Each cartoonist creates his own style, his own character and his own interpretation of the situation. Newspaper comic strips and some of the popular magazines show the great variety of styles employed by different cartoonists. Some cartoons are drawn with more realism than others, but this typifies the individual style of the cartoonist.

EXPRESSIONS

The one set of rules generally accepted by all cartoonists pertains to the facial expression. The facial expressions are produced by the movements of the movable parts of the face, the mouth and muscles around it, the eyelids, eyebrows, even the wrinkling of the nose or forehead. Figure 18-1 shows a number of emotions expressed simply by changing the shape or position of the mouth, eyes, and eyebrows. When the face assumes a happy expression, the parts of the face are lifted. The corners of the mouth are pulled up and out. The cheek muscles are bunched by this action so that the lower lid of the eye is pushed up and the eye is almost closed. The eyebrows are raised.

Figure 18-2.

To make the face unhappy, the corners of the mouth are dropped. Notice that the lines of the eyebrows are lowered but are a little higher toward the bridge of the nose, giving a pathetic cast to the face, whereas in the next figure, determination is expressed in part by the brows that lower toward the nose, as well as by the out-thrust chin and lower lip.

In anger, the brows are pulled still further down, and a frown wrinkle forms between them. Surprise is expressed by raised brows, a dropped chin, and widened eyes. Horror is an exaggeration of surprise. The brows are arched, as well as raised. The mouth is pulled open causing tense lines to form from the nostrils downward. The eyes are widened still further, until they look as if they might drop out. The hair looks as if it were standing on end.

Smugness is expressed by a slight smile, raised brows, almost closed eyes, and the head tilted backward. Scorn is shown by lowered brows and lowered corners of the mouth which form harsh lines downward from the nostrils. Pathos is expressed by raised eyebrows which are higher toward the center of the forehead, closed eyes, and slightly parted lips with the corners pulled slightly downward. The head, relaxed and tilted to one side, and the rumpled hair add to the pathetic appearance.

Along with the facial expressions, the body's movement and character should fit the emotional appearance of the face.

There are occasions where these rules of expression are not used. Although it has been stated that the rules of expression are generally accepted, let it be reemphasized that as a cartoonist, you are bound to no rule except that of good taste.

POSTER WORK

Posters are used for a wide variety of purposes in which a message is to be communicated in the fastest possible way. Cartoons are widely used in poster work because of their great attention getting qualities. There are numerous types of posters, with safety and announcement posters composing the greatest portion. In safety posters, the use of a cartoon character confronted with the various safety hazards is

10182

more desirable than the use of a photograph of a human being in the same situation. Photographs showing an unfortunate person twisted or mangled in pain or death are quite repulsive to the majority of people and are readily shunned. If the audience will not look upon the poster, no message is communicated and the purpose of the poster is defeated. By using a cartoon character, say in a safety poster about electricity, you can show the character being shocked or worse; this is impossible with photographs.

When a large series of safety posters is to be created, it is often advisable to use just one or two cartoon characters in the series. This allows the audience to quickly associate the character with all of the obvious hazards around them and they will usually be more responsive to the poster series.

CAPTIONS

Ordinarily, there are two types of cartoons. Those that are a sort of pantomime—all action and story telling in the picture, and the caption or punch-line type cartoon. In many instances, it is the caption, or gag or joke that inspires the cartoonist in his drawing. Captions are kept as short as possible. The drawing should be of such nature as to need only a slight emphasis from the caption to achieve its objective.

In as much as it is next to impossible to instruct a person in the art of writing captions, since it would be like trying to teach a person how to tell jokes, we will cover only basic cartoon drawing.

Figure 18-3.

Figure 18-4.

CHARACTER CREATION

The range or limit of different characters a cartoonist can draw is limited only by his own imagination. The most important part of a cartoon character is the face, which controls the mood and emotional expression. The head is usually drawn in the shape of an oval, and a few lines are placed to indicate the eyes, nose, mouth and ears. The head does not have to be in the shape of an oval, though; it can be any shape you want. You can use any basic shape, and by changing the shape of just two or three of the facial features, entirely different characters can be created as shown in figure 18-2. It is also possible to use the same character for two different types of people by simply adding a beard or a shave and the type of clothes the character is wearing. This is shown in figure 18-3. The two characters have identical lines with the exception of the beard, uncut hair and shaggy clothing. The business man was drawn by tracing the main lines from the drawing of the bum. This procedure can be repeated to create an almost unlimited number of different characters. Figure 18-4 shows just a few of the many possibilities.

10183

oscillator load impedance (and hence power output) that result when the oscillator frequency is varied. A good impedance match is particularly important if the line between local oscillator and probe is long. To insure a relatively constant load impedance for the oscillator, a resistance disk type of attenuator is often inserted in the local oscillator line, as shown in (A), in order to terminate the line section between oscillator and disk in its characteristic

1016

Figure 18-5.

Figure 18-6.

When you are required to create a cartoon character, one of the most important factors to consider is the end use of the cartoon. If the job order, for example, calls for a series of cartoons to be presented before a large civic audience, you should consider the interests and background of the group. Perhaps a comic element may be found in the incongruity of historical situations as compared with a comparable modern situation. Perhaps some factor of local history or local current popular interest can be worked into the presentation.

The use of cartoons in group presentations is highly effective because it both gains the attention of the audience and fosters relaxation. This also helps to build up an eagerness in the audience for the remainder of the presentation.

CHARACTER AND SUBJECT ASSOCIATION

When cartooning, you do not always have to create a character with only human characteristics. The job may call for animation of a piece of machinery, a ship, an airplane, or any number of objects. This animation of objects is usually enthusiastically received when the audience is familiar with the depicted objects. Figure 18-5 shows an animated submarine and dolphin which could be very successful for any work pertaining to the submarine force. This design would not necessarily be as successful, though, if used at a Naval Air Station. In the case of a Naval Air Station, characters similar to those in figure 18-6 would be much more appropriate. Figure 18-7 introduces LT ALBRATROS, USNR, and his crew man, airdale 3rd class WALLY DUMBPELL. These types of characters are highly acceptable and have a wide range of uses.

Figure 18-7.

10184

of people and with people from certain areas. These symbolic features have been associated with certain types of people for so long that the public will instinctively relate a certain appearance to a particular type of person. For example: the hillbilly right out of the hills. His symbolic attire is a torn checkered flannel shirt, bib type overall with patches, a rumpled wide brim hat; he is also usually in need of a haircut and a shave. He is often shoeless and carries a long barreled squirrel gun.

Although this may not be factual in relation to backwoods people, he is usually pictured as rather ugly and has a warm relationship with his jug of corn whiskey.

The female from this area is usually illustrated in two styles. One, the beautiful, well proportioned lass, and the other one, whose appearance more closely parallels the man's appearance. These three characters are shown in figure 18-11. As you can see, one look at the characters will place them in your mind as hillbillies, and you will have no trouble getting them mixed up with the characters from a more affluent society in figure 18-12.

You should, when possible, use the established public impression that is readily accepted for a particular type of person. There is a symbolic type for nearly every type and for every geographical area in existence, including foreign nations. The list is unending; and the following illustrations show but a few of the long, long list of possibilities.

Figure 18-13.

Figure 18-14.

Figure 18-12.

Figure 18-15.

10186

You will see in these examples that some of the characters are drawn as having large noses while others are drawn having short noses. You must experiment in cartooning just as in all phases of illustrating in order to find just the right design, the right nose or mouth, type of eyes or hairstyle, to fit the character so that he will blend into the situation properly. You will find that cartooning is more than mere doodling; it takes practice, experimentation, more practice and a firm determination to become a good cartoonist. The cartoons shown in this chapter are the writer's creations—his style of drawing. Although it is proper for you to copy them for practice, it is essential for you to develop your own style of cartooning before you can consider yourself a cartoonist of any caliber. Remember, it is your style; develop it to fit your abilities and needs.

Just as there is an almost unending list of different types of people, many of these can be seen as two distinct characters, the good guy and the bad guy. For example, there are both good cowboys and bad cowboys (fig. 18-13). In cartooning, it is not necessary for the good guy to always win. It often adds to the humor of the situation when the bad guy wins.

In the world of music there are many different types of personalities. There is the classical musician and the modern day, no talent, hip swinging howling type of performer (fig. 18-14). Of the latter, some have almost lost their identities as humans (fig. 18-15).

Figure 18-16.

Figure 18-17.

Some of the people of foreign countries offer themselves as excellent specimens for cartooning. The people of Germany (fig. 18-16) have always been well known for their aristocratic, military leaders and the Bavarian-type costumes and beer steins. Typical Russian cartoon characters are shown in figure 18-17.

Remember, it has already been said that not everybody will like your cartoons. What will fracture one group's funny bone may bring screams of protest from another. Solution: always know your audience.

The different people of the world have many different characteristics and costumes and it is most interesting to work up several different interpretations of each of them. So far, you have been shown a few examples.

When you are drawing a cartoon depicting a certain nationality, or race or period of history, it is extremely important to use the correct costume on the character. This aids in his identification and correctness, and when done well, adds to the humor of the character. You may be able to see this in the drawing of the Roman toll collector (fig. 18-18), and the drawing of the Viking and Italian explorers. (fig. 18-19). In any cartoon, not only must the costume be correct for the character, but any supporting characters, the stage or background if there is one, all must be in place with the main theme. The pattern must be consistent, with all particulars related. In cartoons, the background is usually greatly simplified and reduced to just those elements essential to clarify the picture. In some cartoons there is no background at all;

10187

Figure 18-18.

Figure 18-19.

10188

Figure 18-20.

other times, the background may be highly detailed. This again is usually a choice of the cartoonist. The use of background is usually determined by the style of the cartoonist. Most frequently, a cartoonist will use no more background than is needed to identify his character to a specific area or location.

You can also use cartoons effectively to make good-natured fun of someone or some group. This points out again that taking any situation, person, or group, you can create an effective cartoon out of it. For example, figure 18-20 is a cartoon prepared by a DM who is not an ex-Seabee for the benefit of the many DMs who are ex-Seabees.

CARICATURES

Drawing caricatures is very much like having the subject stand in front of the bent mirror found in carnivals and penny arcades. The mirror distorts and exaggerates the features, but does not add or subtract anything not already existing about the subject. The cartoonist does the same thing. The predominant features are exaggerated or distorted; but you must be careful not to get away from the character.

Don't offend; exaggerate but be reasonable. When possible, incorporate a hobby or anything identified with the subject. "Local color" always helps for a truer characteristic.

Capture at least one outstanding feature—a typical expression or mannerism. Put that down (slightly distorted) and draw around it. Once the head is drawn, the body can be drawn in. A good proportion for caricature is 2/3 head, 1/3 body. The only possible way to learn to do caricatures is to practice. Strive for a likeness, then add small distortions to add humor.

10188 10189

CHAPTER 19

VISUAL PRESENTATIONS

Early man communicated visually by scratching on the walls of his cave and, incidentally, transmitted to us, many years later, ideas and thoughts of his life and culture. From this beginning, man developed tools to help him in the job of communications: the stylus and clay, papyrus, chalk and slate, various drawing tools, and, eventually, the printing press, the camera and the projector.

NEED FOR VISUAL AIDS

CLASSROOM INSTRUCTION

Nowhere in the organization of today's Navy will you find a greater use of visual aids than in our Navy schools and training courses both ashore and afloat. Regardless of the field of study, every passing day finds more students and more subject matter crowded into the classrooms. Instructors today use many audio-visual aids, from diagrams of electronic circuits to charts of human anatomy.

MILITARY BRIEFINGS

Considering the Navy's complexity and size, how can our military commanders keep up to date on statistical information? Every day large amounts of statistical data and operational information are gathered to guide these men who must make the decisions. But this data must be presented clearly and rapidly to those who need to know and act. With the use of audio-visual aids, information can be prepared and projected for viewing within minutes after receipt. These aids may be easily changed and updated at a very low cost. The use of audio-visual aids has made it possible for quicker action to be taken and for vital information to be covered more fully than ever before.

The visual aid equipment used in most military briefings includes the various kinds of projectors described in chapter 8. It is part of your job as an illustrator to make the transparencies to be used in these projectors.

On a more permanent nature, each Naval District has training aids facilities which provide Transparency Catalogs, NavPers 301551-1, Film Catalogs, NavPers 10000, Three Dimensional Visual Aid Catalogs, NavExos P-530-2, and Graphic Visual Aid Catalogs. Quite often the visual aid you need has already been constructed and is cataloged.

Whenever possible, check with these catalogs and secure from proper source the training aid you desire.

HANDMADE TRANSPARENCIES

The simplest of all transparencies for overhead projectors is made by drawing on a clear sheet of plastic with a black grease pencil. The drawing can be easily erased with a dry cloth and the plastic may then be reused.

Grease pencils make lines and letters which are thick and bold. For finely detailed drawing or writing on plastic, a specially designed pencil is available commercially which has an easily sharpened lead which holds a point well. This pencil will write well on any surface, including glass.

The use of ink on acetate plastic sheets offers some problem because the surface of the plastic is nonabsorbent. With some care, however, it is possible to draw with several kinds of special black and colored inks which will adhere to clear plastic. To obtain colored

10190

lines on plastic, you can draw with felt-tipped marking pens which produce transparent colors on the plastic.

DRAFTON, LUMOCHROM

Drafton plastic has a finely etched and highly transparent surface which accepts pencil lead. Lumochrom pencils for plastic transparencies have special leads which pass light and permit brightly colored images to be projected on a screen.

Because Lumochrom pencils are sharpened like ordinary colored-lead pencils, you can easily do fine detailed work and produce multicolored transparencies with a minimum of effort. The colored pencil marks can easily be removed with an ordinary eraser and the plastic sheets can be used again. The color image can be made permanent by coating the etched surface with a plastic spray or by spreading on a coating solution with a Polaroid Print-Coater.

OPAQUE-COATED ACETATE/PLASTICS

Another type of handmade transparency can be produced by using acetate plastic sheets having a coating which blocks the projection light. These are available commercially or can be made by painting a transparent acetate sheet with black paint. Using a stylus or pencil, the image to be projected is cut away through the coating. When projected, the cutaway areas appear in luminous white on the screen, while the rest of the screen remains dark. This type of projection makes for easier viewing, especially when there are a number of transparencies to be projected.

COMMERCIAL AIDS FOR EFFECT

ADHESIVE LETTERS AND SYMBOLS

There are several brands of plastic letters and symbols which can be used in making transparencies. By using these stick-on letters and symbols, you can easily do fast lettering of a professional quality. Most of these stick-on letters work well on masters for diazo reproduction.

ADHESIVE SHEETS

Large adhesive color sheets are available for covering large areas of a transparency. Unwanted portions are simply trimmed away. Among the trade names for adhesive color sheets are ARTYPE, BOURGES, CRAFTYPE, ZIP-A-TONE and BLUZIP.

PATTERNS AND SYMBOLS

Any gum-backed material may be used for making patterns, symbols, and silhouettes for transparencies. Letters photographically reproduced on film can also be taped in place on clear plastic sheets to produce sharp, clear images. Several machines which produce such lettering are available under the trade names of HEADLINER, PRO-TYPE, and FILM-O-TYPE. With many of these materials, the addition of color to the transparency helps form an attractive and effective image on the screen.

MECHANICALLY PRODUCED TRANSPARENCIES

LIFT METHODS

A unique method of making transparencies is to "lift" a picture from a magazine. Some magazines are printed on paper that has a clay coating. Ink can be lifted from this surface and transferred to a sheet of plastic for projection in black and white or full color.

To find out if the picture you want is printed on clay-coated paper, moisten a finger and rub it on the corner of the paper. If a white deposit rubs off, the sheet is clay-coated and you can lift a transparency from that page. Only one transparency can be lifted from any one picture because the process destroys the picture. Transparencies may be lifted by either the dry mount method or the rubber cement method.

Dry Mount Method

In the dry mount method of lifting pictures, a sheet of specially coated plastic, such as Seal-Transpara film, is placed face to face with the printed picture; then the plastic sheet and paper picture are placed between polished metal plates in a dry-mounting press. These sheets are then heated under pressure for 5 to 10 minutes. When the sheets are removed, the plastic and the picture are laminated. The laminated sheet is soaked in warm water until the paper loosens and comes off. The paper

10190
10191

may be loosened by rubbing the plastic surface with the hand. The clay-coating residue is sponged off and the plastic sheet, which then contains the picture, is allowed to dry. The image is then coated with a plastic spray to make the sheet more transparent for projection.

Rubber Cement Method

A plastic sheet is also used in the rubber cement method of lifting pictures. An even coat of thinned rubber cement is brushed on both the picture and the clear plastic. When the cement is dry, the two coated surfaces are carefully pressed together, and the air bubbles are smoothed out with a roller. The combined sheets are then soaked in warm water to loosen the paper backing. While the picture is in the water, the remaining clay-coating and paper fibers are gently sponged off. When dry, the plastic should be protected and transparentized by a coating of a plastic spray.

Lift transparencies project well and make excellent masters for diazo transparencies and paper copies.

THE DIAZO PROCESS

The foregoing section has described how to make transparencies for overhead projectors by hand and by using mechanical processes. Now we will look at a method which offers even greater opportunity for you to make top quality visual aid materials. This is the DIAZO process.

THE CHEMISTRY OF DIAZO

Let's examine the chemistry of diazo in its simplest sense.

Diazo is directly associated with the chemistry of azo dyes. These are the dyes frequently used to color the clothing we wear and other fabrics. With diazo reproduction materials, the dye-forming potential is present in the form of molecules of "diazo salts" and a "coupler." In "dry-developing" diazo materials, these elements are suspended in a "stabilizing" solution and coated on the surface of acetate, paper, cloth, glass, and a myriad of other bases. These materials are termed "dry-developing" because they don't require contact with, or immersion in, any liquid solution to create their dye image. The hard, sensitized emulsion on dry-developing foils will react to form a dye image of brilliant azo color when exposed to ammonia vapor.

Why ammonia vapor? The stabilizer in the emulsion of diazo materials is acid by nature. The molecules of diazo salt and coupler are separated by this acid stabilizer. They are prevented from combining to form colored dye until you are ready for them to do so. When you are ready, you expose them to ammonia vapor. Chemically alkaline, this vapor neutralizes the acid stabilizer. With the acid neutralized, the diazo molecules and other coupler molecules are free to unite and form the azo dye. This then is how to "develop" diazo images. You do not need hard-to-use liquids; all you need is ammonia vapor—vapor which does not wet the foil, but develops full, rich color in a matter of seconds and leaves the foil dry, fog-free, permanent, and ready to use.

EXPOSURE AND DEVELOPMENT OF DIAZO FOILS

Before development, the diazo emulsion is sensitive to light just as a roll of photographic film is sensitive to light. But there is a big difference. Whereas photographic film is very sensitive to almost any kind of light, the emulsion on a diazo foil is moderately sensitive to only one kind of light: ultraviolet. Although not greatly affected by indoor lighting, the diazo emulsion is highly sensitive to all ammonia vapor. Because of this, special care must be taken to store all diazo emulsion products away from ammonia or ammonia vapors. A well-ventilated room with controlled temperature is the best storage space for diazo materials.

ULTRAVIOLET USED TO PRODUCE A VISUAL IMAGE

To produce a meaningful diazo transparency, the diazo foil must react in a way similar to photographic film. It must "take a picture" and reproduce an image that contains the information you wish to show. Since diazo foil is appreciably sensitive only to ultraviolet light, this is the kind of light used for our "picture-taking" exposure.

When the foil is exposed to a source of ultraviolet light and certain areas are protected with some sort of light-blocking material, the unprotected emulsion on the foil will have its undeveloped color destroyed or faded, while the

10192

protected emulsion on the foil will remain intact. Then, when this light-exposed foil is exposed to ammonia vapor, those areas that have been protected will appear as full-color dye images and the rest of the foil will remain clear.

To produce a transparency with a diazo foil, you place a transparent or translucent sheet containing an opaque image over the foil when you expose it. The opaque image will appear on the foil when it is developed by the ammonia vapor. The translucent or transparent sheet which contains the opaque image is called a diazo "master."

PREPARATION OF DIAZO MASTERS

An almost unlimited range of basic materials can be used in the preparation of diazo masters because there is only one principle that must be observed: the passage and blocking of ultraviolet light. In other words, a diazo master must be so constructed that certain parts of it will block ultraviolet light and the other parts will pass the light. The basic material normally used for the diazo master is translucent paper. Tracing paper is translucent; it will permit passage of light. Further, it is a simple matter to affix to its surface other materials such as inks, tapes, and pencil marks which are opaque and block light. A tracing paper which will pass maximum light as well as provide a desirable working surface for affixing opaques is best. There are several tracing papers which are expecially useful as master material for the preparation of overhead projection transparencies by the diazo process. Some of these are Ozalid, Visi-tran, Tecnifax Tecnivellum, and K & E Albenene.

Tracing Paper Masters

After the tracing paper has been selected, the next step is to create a visual image with materials that will block the passage of light. Such materials are lead pencil, grease pencil, opaque ink, photographic film, paste-up letters, shading sheets, graphic illustration materials, and tape. These used together or singly will reproduce well.

Preparation of a master is limited only by your imagination, ingenuity and the instructions of the originator. You can trace an illustration from a book such as this, for instance, with a good black-lead pencil. From this tracing you can easily produce a brilliantly colored or black and white foil for immediate projection.

In designing your transparency master, keep in mind that the image area must block ultraviolet light. Make strong, dense lines and affix materials that have good light-blocking properties. There are a tremendous number of production materials available; experiment with as many as you can to find which ones suit your needs best.

Plastic-Sheet Masters

If tracing paper makes a good diazo master because it is translucent, then obviously a base material that is transparent will also make a good master. The main reasons for using tracing paper as the base material are that it costs less than plastic and it offers a textured surface that is far better to write and draw on than plastic film.

However, any clear film will serve very well as a base on which to create an image for diazo reproduction. This means that the section in this chapter on handmade transparencies can serve a double purpose, since almost any transparency produced by the methods discussed will serve as an excellent master for diazo printing.

Plastic Tape For Paste-Up Work

Attaching materials to masters would be a problem if we had to use glues and pastes. This isn't the case in diazo printing, because with diazo you can use translucent and transparent plastic tape in almost all of your paste-up jobs. The tape will pass light during exposure; so, even though it may be visible on the master, it won't reproduce on the printed and developed Projecto Foil.

In selecting plastic tape for this purpose, you'll get best results from one having a thin base and high translucency. Scotch No. 810 Magic Mending Tape is highly recommended for this purpose.

Use of Orange Carbon Paper

Since diazo materials print their most dense images from masters that have lines which block light effectively, orange carbon paper is an excellent help when preparing drawn or typewritten masters.

A sheet of orange carbon is placed underneath the tracing paper with the carbon side up. When you write or draw on the master, the orange carbon will transfer to the back of the master

10193

resistance. An alternative to the resistance disk is a piece of lossy cable which may be inserted between local oscillator and mixer assembly. (NOTE: Lossy cable uses resistance wire for the center conductor. An example of lossy cable is RG-21/U.)

Oftentimes mixer assemblies include, in addition to the circuit that supplies IF echo signals, a separate mixer for generating IF signals for the automatic frequency control circuit. An example of a 3-cm mixer assembly of this type is shown in figure 12-34 (A).

Local oscillator power and RF echo signals from the TR cavity are coupled into waveguide 1, which serves as the echo signal channel. A crystal extends between top and bottom walls of the guide, the lower end of the crystal being isolated from the guide by means of a dielectric washer, Echo signal voltages in the intermediate frequency band appear between the lower end of the crystal and the waveguide and are conducted to the input circuit of the IF amplifier, usually over a coaxial cable.

Waveguide 3 is similar in construction to waveguide 1 and serves as the AFC channel. Power from the local oscillator and a small amount of the transmitter power are applied to the AFC crystal, and IF signals for the AFC circuit are derived at the lower end of the crystal mount, as before. Attenuation between the main guide and guide 3 is provided by means of a circular waveguide section operating below cutoff. Sometimes a disk type attenuator is included in the circular section to reduce further the amount of transmitter power reaching the mixer assembly.

The local oscillator tube is mounted above waveguide 2 in a manner that permits the local oscillator output probe to extend a short distance into guide 2. The coupling probe may be displaced slightly from the center of the transverse axis of the guide in order to obtain a load impedance for the oscillator which yields a reasonably uniform power output over the tuning range.

Local oscillator power is coupled from guide 2 into guides 1 and 3 through coupling apertures located in the side walls of the guides. A matching post and tuning screw extending from top and bottom walls of the guides at the aperture locations serve to regulate the amount of local oscillator power coupled to the mixer circuits.

For optimum performance of the radar system, the echo signal channel of the mixer should provide a matched load impedance to the waveguide transmission system. The elements that determine the mixer input impedance are shown in the equivalent circuit (B). The equivalent circuit is derived by dividing waveguide 1 into three sections of lengths βd_1, βd_2, and βd_3 and representing the sections by equivalent lengths of transmission lines (lines A, B, and C in fig. 12-34 (B)). The signal current generator I_s in shunt with R_c in the equivalent circuit accounts for the portion of the RF system between antenna and mixer. The coupling aperature between local oscillator and mixer guides (guides 1 and 2) is represented by a variable inductance L, and in shunt with L is an impedance Z which accounts for the impedance seen in the direction of the local oscillator guide. The parallel combination of L and Z terminates a quarter-wave section of line which is in shunt with lines A and B. At the echo signal frequency, the impedance L and Z in parallel is maintained small enough in comparison with the characteristic resistance of the quarter-wave line to make the imput impedance of the quarter-wave section extremely high and hence the amount of echo signal power entering the local oscillator guide is extremely small.

The crystal is located at the junction of lines B and C, as shown in figure 12-34 (B), and across the crystal output terminals is a series RLC circuit. The counterpart of the RLC combination is an RF choke in the IF output lead of the mixer. The choke prevents RF signals from entering the input circuit of the IF amplifier.

The length of shorted-end line C must be such that the input admittance of line C, in shunt with the RF admittance of the crystal, provides essentially a matched load for line B. Varying the length of line C changes the susceptance component of the total admittance at the crystal location. A length of approximately $\lambda/4$ is usually preferable in order to minimize changes in admittance with frequency.

BALANCED MIXERS

The noise introduced into the input circuit of a microwave receiver by the local oscillator may be reduced appreciably through use of a balanced mixer. An input circuit of this type employs two crystal mixers connected so that the local oscillator voltages applied to each crystal are in phase and the echo signal voltages at each crystal are 180° apart in phase.

1017

sheet and, in effect, give you double-weight image—your drawing on the front and the carbon on the back. This added opacity assures maximum print density.

When typing a master, put the carbon in the typewriter in back of the master with the carbon side facing you. This will also create a double-weight image: the typewriter-ribbon ink on the front and the orange carbon on the back.

You may wonder why the carbon paper is colored orange. The reason is that orange blocks ultraviolet light better than most other colors. Whenever you need a master of maximum opacity, use orange, yellow, sepia, or brown.

INTERMEDIATES

In the tremendous line of diazo printing materials are products which have special uses as "intermediates." These materials, when made from "original" masters, can be used as permanent "duplicate" masters for repeated or quantity reproduction. Intermediates also offer you opportunities in the production of many-celled overlay-transparencies because they may be corrected and amended and then used as excellent masters for colored-cell reproductions. Since orange, sepia, yellow, and brown are good light-blocking colors, intermediates usually have sepia or brown images on translucent paper or foil.

Reversal Foil

It is sometimes desirable to project clear lines on a colored or black background. You can produce such negative images from positive masters by using Ozalid Reversal Foil.

Expose Reversal Foil from your master as usual and develop it. The negative image which forms is a yellow-orange color, with light areas where the master had dark areas and vice versa.

After the foil is fully developed, rinse it in water to remove unused light-sensitive chemicals, thus "fixing" the image. This rinsing is simple; just dip the foil for 10 seconds in hot water, or rinse for a minute in warm water. To speed drying, blot the foil between paper towels; DO NOT RUB. When dry, the Reversal Foil is ready for use.

Reversal Foil does not project well itself because of its low visual color density. But this image, being orange, blocks ultraviolet light; so it is a good "intermediate" master from which you can produce a sharp, clear image on a foil in the color of your choice.

Photographic Negatives

For photo negatives which are not visually understandable in the negative, you do not have to go through the time-consuming and expensive photographic process to convert these negatives into usable positive transparencies. You can use Reversal Foil and Ozalid Continuous Tone Projecto Foil. Reproduce your film negative on Reversal Foil to produce a positive intermediate, and then use that positive to make foil transparencies. Continuous Tone Projecto Foil gives faithful reproduction of the photographic tones in black, and the other foils make striking, colorful, positive transparencies. Reversal Foil eliminates the need for wet photographic processing in converting photo transparencies. Brown or sepia foils, for example, make excellent intermediates. To make an intermediate from your master, expose and develop a sheet of intermediate foil or paper just as you would a foil transparency. Be sure that it is completely developed so that the image is as dense as possible.

An intermediate paper print can be used as an inexpensive transparency master for distribution or exchange.

Transparentizing Solution

Printed pages of photographs which are blank on one side but not transparent enough for good diazo printing can be made more transparent with a transparentizing solution. The solution is applied liberally to the back of the sheet, and then the excess if wiped off with a soft cloth or cotton. Frequently, transparentizing will make the copy transparent enough to be duplicated directly on a foil.

PREPARING MASTERS BY PROJECTION

You can make a master by drawing from a projected image. Attach a sheet of suitable tracing paper to a drawing surface, and, using either the standard 35 mm slide projector or the opaque projector, enlarge the image by projecting it on the paper. You can adjust the projector distance and the focus so that the appropriate margins are maintained. When the image is sharp, trace the image with a pen or a soft pencil.

10194

MASKING TECHNIQUES

There are times when large areas of an intricate design must be reproduced in a solid color. The fastest and easiest way to block out a large intricate area is by "masking" it with an opaque material. Here are four methods of masking.

Masking tape. Using a light-table, overlay a sheet of suitable tracing paper on your master. Ink a clean, opaque band about a quarter-inch thick around the inside edge of the area to be masked. Let the ink dry; then cover the area inside the inked band with masking tape. When printed, the masked area will produce a solid color on a foil transparency.

Opaque paper. Place a sheet of tracing paper over your master. With a sharp pencil or fine pen, trace the outline of the area to be masked. After tracing, expose this master to a card-weight diazo paper. Use a knife or scissors to cut out the image area; then mount it with Scotch No. 810 tape in position on your master. The masked area will produce a solid, even color on Projecto Foil.

Intermediates. Fully develop an unexposed sheet of brown foil. Place this over the master. You can see the lines on your master through the foil. Use a stylus or other sharp instrument to scratch away the color on the foil in a line around the outside of the image area. When the outline is complete, remove the rest of the unwanted color by cutting around the outside with scissors or an Xacto knife. Tape the brown foil image onto a sheet of tracing paper in the proper position. When the foil is printed, the brown image will reproduce as a solid color on a foil transparency.

Reversal Foil. When the area to be masked is larger than the unmasked area, Ozalid's Reversal Foil can be a great time saver. First, overlay a sheet of tracing paper; then use one of the previously mentioned methods to mask out everything except the image area. Expose this to a sheet of Reversal Foil and develop the foil. The resulting reverse print will reproduce the unmasked area in a yellow-orange color. This reversed foil will reproduce as a solid color on a foil transparency.

OVERLAY MASTERS

The overhead projector does not require that projection materials be mounted in tight, unmovable packets as is required with other types of slides. This means that "overlay" transparencies can be used with all their outstanding communication effectiveness and visual impact.

Overlay transparencies are made up of a base transparency or "cell" with several additional transparencies or cells mounted on top. These additional cells are positioned so that they may be removed or added to the total visual picture as desired by the user.

With overlays, a series of ideas or instructional points can be projected in any desired order with one multiple-celled transparency. In this way, you can visually develop an idea or system. Also, you can visually separate an idea or system into its components.

Tracing Method of Preparation

The first step in making overlay masters by the tracing method is to prepare a master drawing, in actual size and in complete detail, on a sheet of tracing paper. Having completed your master drawing, add registration marks in the top and bottom margins.

Tape the master drawing on a light-table to make it easier to register subsequent drawings. Take another sheet of tracing paper and place it exactly over the master drawing. Secure the top corners with tape. Leave the bottom of the second sheet free so you can recheck areas on the master if necessary. Place registration marks on the second sheet corresponding with those on the master drawing.

Ink in or opaque the area of the master drawing to be represented by the first overlay. Remember—only the areas that you want for this overlay are filled in on this sheet. For each additional overlay, place a sheet of tracing paper in register over the others and repeat the process. With this technique you can quickly produce separate masters for multicell overlay transparencies.

Nonreproducible Blue Method of Preparation

One intermediate diazo material which is excellent for the production of multicelled transparencies is the nonreproducible blue-line intermediate paper. This translucent paper is coated with a thin diazo blue emulsion which, when developed, is visible to the eye but will not reproduce when reprinted on another diazo material. It does not block ultraviolet light.

10195

This intermediate is used to produce multi-colored transparencies as follows.

Make a nonreproducible blue-line intermediate of your original master for each color you wish to produce in the finished transparency. Use a different blue-line print for each color. Follow the blue-line image and ink in or mask the areas you want to appear in color. Then print each masked paper intermediate onto the appropriate colored foil. Only those areas you have inked in or masked will be reproduced. Mount these "color-separated" foils in register and you have a multi-colored transparency for projection.

It is easy to correct an overlay master drawing if a mistake is made. If you should accidentally fill in all or part of an area on an overlay, simply use a knife or other sharp instrument to cut away the unwanted image. When reproduced on a foil transparency, the cutout area will be invisible. Or, if a correction is necessary, cut out the area to be corrected and replace it with a clean piece of tracing paper held in place by Scotch No. 810 tape. Then make your correction on the tracing paper patch.

TRANSPARENCY MOUNTING TECHNIQUES

Almost any opaque material may be used to mount your transparencies for overhead projection. Cardboard, heavyweight paper, and even file folders will do the job. Just cut out a section in the middle to serve as the aperture and fasten your transparency in place. The size of the aperture cutout will depend on the size of the projector used. For a 10 x 10 inch aperture, the recommended dimensions for the mount opening are 7 1/2 x 9 1/2 inches. This gives you ample border around an 8 1/2 x 11 inch transparency to permit easy fastening to the mount.

There are a number of mounts available commercially for use with the 10 x 10 inch overhead projector and designed to accept either vertical or horizontal transparencies. Some of these are the Ozalid Projecto Mount, the Tecnifax Fileable Transparency Mount, and the K & E Gemini Transparency Mount, all with a 7 1/2 x 9 1/2 inch aperture.

Mounting a Single Image

Regardless of the type of mount used, the simplest way to attach your transparency is with pressure-sensitive tape such as plastic or masking tape. Simply tape all four edges of the transparency to the underside of the mount. Using the bottom surface makes a more attractive mounting, assures a flat projection area, and leaves the top of the mount free for notations and cues. Even when mounting more than one sheet, it is better to tape them all to the underside of the mount.

Overlays

Overlays are usually hinged at the side of the mount's opening so that they can be swung into position on the projector. However, there are several other ways of mounting overlays. If you want a flexible sequence with the overlays, hinge them on all four sides of the opening. Trim or stagger each overlay so it will fall into place easily. If the overlays are to be added in a given sequence, hinge all of them on the side of the mount opening so that they will always fall in proper order. You can make combinations of these mountings so that some elements are added in sequence while others are inserted as desired.

Roll Mounting

In some instances, you may want to have your transparencies in a fixed sequence and in a roll for easy carrying. Just tape them together, edge to edge, and roll them on a core the size of the roll-holder on the projector. (Don't roll handmade transparencies which have adhesive letters or patterns; they may stick together. Make foil transparency copies, and you can tape and roll the copies.) When projecting a roll of prepared transparencies, place a transparency mount on the projector to mask the aperture to the size of the transparency image area.

Progressive Development

Using overlays, you can "build the unknown on the known," and add elements to your visual aid as you speak. This basic instruction technique is shown in figure 19-1.

Progressive Disclosures

An effective way to present a visual picture during projection is through "progressive disclosure." This effect is achieved by using overlays and removing segments of the total

10196

Figure 19-1.

Figure 19-2.

10197

image to disclose secondary elements. A progressive disclosure effect can also be achieved by covering all of a portion of the transparency with an opaque sheet, such as cardboard, and sliding it off the image a little at a time during projection. Another progressive disclosure effect is possible when an opaque covering is cut into sections so that parts can be lifted off as you disclose different areas on the transparency. This method permits a flexible sequence. These techniques are illustrated in figure 19-2.

TRANSPARENCY DESIGN

The essence of effective visual communication is the transmission of ideas as directly as possible. To be effective, a transparency for overhead projection must tell its story through visualized concepts and ideas rather than through the use of verbal symbols. Projection of words on a screen cannot ordinarily be considered "visual" communication, for if only words are projected, the viewer must mentally convert these words into his own visuals. You should do the visualizing for the viewer. To do this, you need to plan the design of your transparencies to assure that the intended visual message will come through strong and clear. Such planning is not hard to do. The basic rules are simple and the results will always be worth the effort.

ESTABLISH THE IDEA

Consider carefully the exact message you want your transparency to tell. Condense this message in your own thinking to one basic idea that is as clearcut and independent as possible. Select a primary visual symbol of this idea. This symbol will carry the story; consider it your "star performer." It will carry your message to your audience. No star, of course, works alone. A visualization which is not related to things within the framework of an idea can't communicate for us.

SET THE STAGE

Since the star performer alone can't tell the visual message, you must set a stage for it. Determine the secondary elements in your idea that support and identify the primary symbol. These elements will establish the environment in which the idea will be established. Consider all of the secondary elements that might possibly enhance and assist the star to communicate.

Figure 19-3.

10198

KEEP IT SIMPLE

Just because you can think of many secondary elements, don't try to use them all! Be particular and select only those that are absolutely needed to tell the story. Reduce the elements to an absolute minimum. You will notice that these rules are very similar to those in pictoral composition in chapter 13. Figure 19-3 shows the relationship between a single, but effective layout, and a layout which is cluttered and confusing.

LETTER SIZE

Since most transparencies for overhead projection incorporate some verbal symbols to support the visualization, lettering and letter size are important considerations when producing a transparency. Figure 19-4 shows a guide for good lettering on transparencies.

Figure 19-4.

POLARIZED LIGHT

Polarized light can be used in several ways with the overhead projector. You can demonstrate the effect of light-polarizing filters, for example, by placing one filter on the stage of the projector and holding the other between the stage and the lens.

As you turn the upper filter, the light image on the screen will change, showing the light-blocking characteristics of the filters. You can show another application of polarized light by placing a small plastic horseshoe on top of the bottom filter and exerting pressure on it with your fingers. With the top filter in the correct position you will see, in light patterns on the screen, the effect of stressing the plastic. The Polaroid Corporation has published several instruction handbooks which describe experiments with polarized light.

The principles of light-polarization can be applied to the overhead projector to produce effects of motion and spotlighting on the screen. Several systems of application are now commercially available.

Technamation, for example, utilizes an adhesive-backed special polarizing material (which is applied to the transparency) and a motor-driven, rotating polarizing filter attached beneath the projector lens.

The Visa-Matic Systems uses a polarizing filter on the stage of the projector and light-refracting foils which are cemented to the transparency. The Visa-Matic filter, just beneath the lens, is rotated by hand to different positions to achieve various effects.

OPERABLE TRANSPARENCIES

Although usually produced only by professional manufacturers, the two-dimensional operable transparency is an outstanding example of a dynamic projection device. Operable transparencies are constructed of plastic components, usually to duplicate the working elements of some mechanical system. Each component is in correct relationship to the others so that a chain-reaction of movement can be created during projection. Internal parts and mechanical systems of machines can be projected and observed for study and identification of components.

10138
10199

TECHNICAL ILLUSTRATION

The purpose of this section is to assist you in visualizing appropriate illustrative approaches in developing training aids. Figures 19-5 through 19-8 show some of the types of views that can be used to meet various requirements for technical illustrations.

Figure 19-5 shows four highly effective types of views. The OVERALL VIEW (fig. 19-5a) is good for visual familiarization, parts identification, construction details and maintenance check charts. The CUTAWAY VIEW (fig. 19-5b) illustrates internal details as in the phantom view and in addition shows the relationship of interior parts to the overall subject. The CROSS-SECTION VIEW (fig. 19-5c) shows functional relationships of parts within a system, especially for identification of intricate inner parts that cannot be properly shown in a cutaway or phantom view. This includes such items as indicating the motion of coil springs or the action taking place in an internal combustion chamber. The PHANTOM VIEW (fig. 19-5d) illustrates internal details as seen thru the external shape or form. These views are used to show the relationship of parts or interior construction in relationship to the unit as a whole. It is also used as a basic view to show relationship of alternate positions such as levers and dials.

Figure 19-5.

10200

Figure 19-6 shows four more types of views which are regularly used and are highly effective. The EXPLODED VIEW (fig. 19-6a) is exceptionally effective for showing parts identification and for assembly and disassembly procedures. It shows a piece of equipment entirely broken down into its separate component parts. The CHECK POINT CHART (fig. 19-6b) shows location of fittings and components requiring lubrication, adjustment or calibration. The ACTION VIEW OF EQUIPMENT (fig. 19-6c) illustrates function or action of equipment. The ACTION VIEW OF PERSONNEL (fig. 19-6d) shows the actual performance procedure for operation or maintenance of a piece of equipment.

Figure 19-6.

The BLOCK DIAGRAM (fig. 19-7a) shows relationship between functions or components. The WIRING DIAGRAM (fig. 19-7b) presents physical representations of components for reference in diagnosis, repair or installation. The FUNCTIONAL SCHEMATIC-PICTURIZATION (fig. 19-7c) presents overall system concept, individual component functions and sequence of operations. The FUNCTIONAL SCHEMATIC-SYMBOLIC view (fig. 19-7d) shows detailed functions of electrical and electronic circuitry and is used for trouble shooting.

Figure 19-7.

CSOI 407

10202

Figure 19-8.

Figure 19-8 shows some examples of charts and graphs generally used for indoctrination. The PIE CHART (fig. 19-8a) shows proportion and percentages. The INTERACTION CHART (fig. 19-8b) shows organizational structure and relationships. The FLOW CHART (fig. 19-8c) shows direction of motion. The LINE GRAPH (fig. 19-8d) accurately shows comparative changes between related subjects. The BAR GRAPH (fig. 19-8e) is used to show complex quantitative comparisons such as yearly output statistics, etc.

(A) PICTORIAL DIAGRAM

(B) AN R-F EQUIVALENT CIRCUIT OF ECHO-SIGNAL CHANNEL

Figure 12-34.—A 3-cm mixer.

As explained below, this method of circuit connection causes the IF components of local oscillator noise to cancel in the IF amplifier input circuit and the IF components of the signal to add. Because of their ability to suppress local oscillator noise and because of certain additional advantages to be discussed later, balanced mixers are often preferable to single-ended mixers. They are presently finding wide use in microwave radar systems.

ABSTRACT - Developed for the Bureau of Naval Personnel, this training manual is to be used by Naval and Naval Reserve Personnel preparing for advancement in the rate of Hospitalman. Part I discusses elementary anatomy and physiology, while Part II outlines elementary first aid and bandaging procedures, and Part III is an introduction to the principles and practices of nursing. Illustrations, photographs, and charts augment the text. A subject index is included. (Author/SB)

BUREAU OF NAVAL PERSONNEL

NAVY TRAINING COURSE NAVPERS 10664-B

PREFACE

This training course is the first in a series of courses written especially for Hospital Corpsmen. It furnishes study material for U. S. Navy and Naval Reserve personnel preparing for advancement in rating. This material contains extractions from the Handbook of the Hospital Corps to provide an overall coverage of the subject to be studied for advancement. Additionally, this course provides source material for personnel responsible for preparing examination questions for advancement in rate to Hospitalman (HN).

The contents are assembled in three parts including an index and a table of contents for ready reference:

Part I discusses elementary anatomy and physiology. Part II outlines elementary first aid and bandaging procedures. Part III is an introduction to the principles and practices of nursing.

The contents conform to the requirements for advancement to Hospitalman as set forth in the Manual of Qualifications for Advancement in Rating, NavPers 18068-B.

Completion of this course is a prerequisite to advancement to hospitalman except as otherwise provided by current BuPers instructions. A Hospital Apprentice is not eligible to take the examination for advancement until an entry is made in his service record that this training course, or its equivalent, has been completed.

The basic principles of a balanced mixer may be explained from the diagram of figure 12-35, which shows two crystals mounted a half wavelength apart (at the signal frequency) between conductors of a coaxial line section. Each crystal is located a quarter wave from the nearer end of the line, and the local oscillator signal is probe coupled to the line at a point midway between the crystals. The output terminals of the crystals are connected to an IF transformer, the primary winding of which is balanced to ground. The signal current generator I_s in shunt with resistance R_c accounts for signals entering the mixer from the TR device.

The local oscillator coupling probe gives rise to two waves traveling in opposite directions in the coaxial line. Assume that at the local oscillator frequency the TR device presents a short circuit to the local oscillator wave traveling to the left in figure 12-35, and that the crystals have identical RF impedances equal to twice the characteristic resistance of the line. Then equal-amplitude, in-phase, local oscillator voltages appear at the crystals. Because of the half-wave spacing between crystals, the RF echo signal voltages at the crystals are also of equal amplitude but are 180° apart in phase. An in-phase relation between local oscillator and echo signal voltages produces an IF signal voltage of one phase, and a 180° phase relation between local oscillator and echo signal produces an IF signal voltage of opposite phase. Thus the two IF echo signal voltages add in the balanced input circuit of the IF amplifier. Because the noise that accompanies the local oscillator signal produces voltage components that bear the same phase relation to the local oscillator voltage at each crystal, the corresponding IF components of noise at the output of each crystal are in phase and hence produce no resultant noise voltage across the IF transformer.

Figure 12-35.—Coaxial line balanced mixer circuit.

In order to realize full benefit from use of a balanced mixer circuit, the crystals should have similar RF impedances as assumed above, and in addition they should have similar conversion gains. Under these conditions of operation, only one-half the available RF power is applied to each crystal, but since the IF signal powers from the crystals add together, the total IF power is the same as that obtained from a single-ended mixer. Since IF components of local oscillator noise are completely eliminated, maximum reduction in overall noise figure is obtained.

An imbalance in conversion gain yields an imbalance in the IF signal voltages obtained from each crystal and also an imbalance in the IF components of local oscillator noise voltages at the crystal output terminals. However, since the IF signal voltages are additive in the crystal output circuit and the local oscillator noise components are subtractive, small imbalances in conversion gains do not seriously affect the overall receiver noise figure.

More important are the effects of a difference in the RF admittances of the crystals. An imbalance of this type causes both the echo signal power and the local oscillator power to divide unequally between the two crystals. As a result, the IF signal power obtained from the mixer is appreciably reduced, and in addition the IF components of local oscillator noise are prevented from canceling completely in the IF input circuit. Crystals intended for use in a mixer constructed as shown in figure 12-35 must be carefully selected on the basis of equal RF admittances in order to insure most satisfactory operation.

A balanced mixer that is superior in several respects to the coaxial line mixer just described is shown in figure 12-36 (A). This mixer employs a waveguide hybrid junction.

Crystals are located in one pair of entries (arms 3 and 4). Usually in a mixer of this type the input circuit of the IF amplifier is also arranged in the form of a hybrid junction.

1019

THE UNITED STATES NAVY

GUARDIAN OF OUR COUNTRY

The United States Navy is responsible for maintaining control of the sea and is a ready force on watch at home and overseas, capable of strong action to preserve the peace or of instant offensive action to win in war.

It is upon the maintenance of this control that our country's glorious future depends; the United States Navy exists to make it so.

WE SERVE WITH HONOR

Tradition, valor, and victory are the Navy's heritage from the past. To these may be added dedication, discipline, and vigilance as the watchwords of the present and the future.

At home or on distant stations we serve with pride, confident in the respect of our country, our shipmates, and our families.

Our responsibilities sober us; our adversities strengthen us.

Service to God and Country is our special privilege. We serve with honor.

THE FUTURE OF THE NAVY

The Navy will always employ new weapons, new techniques, and greater power to protect and defend the United States on the sea, under the sea, and in the air.

Now and in the future, control of the sea gives the United States her greatest advantage for the maintenance of peace and for victory in war.

Mobility, surprise, dispersal, and offensive power are the keynotes of the new Navy. The roots of the Navy lie in a strong belief in the future, in continued dedication to our tasks, and in reflection on our heritage from the past.

Never have our opportunities and our responsibilities been greater.

INTRODUCTION

THE HOSPITALMAN

This training course is the beginning of your career as a member of the Hospital Corps. Created by Act of Congress on 17 June 1898, the Hospital Corps is unique in that it is the only enlisted Corps in the Navy. The heritage of the Hospital Corps is a proud one and you as a Hospitalman must do your part to preserve it.

The duties of the Hospitalman evolve around human lives, their well-being and their health. Prevention of disease as well as treating it, ministering to the wounded and injured, is an occupation as old as humanity itself and one for which we reap the highest rewards.

This book is the bottom rung of your ladder to success in your career as a hospital corpsman. It forms the basis for the skills and knowledge required of you, those vital for better performance of your duties and for future advancement.

Everything you do as a hospital corpsman will have a specific relation to some part or function of the human body and its environment. This training course is the first phase in understanding these relationships.

While each chapter deals with specific parts or functions of the human body, all of them are closely related and in order to effectively do your job as a hospitalman you must have a thorough knowledge of these facts and their relationships.

Part I of this training course covers elementary anatomy and physiology, the study of which is the basis of all medical knowledge. Part II, First Aid, includes elementary first aid and bandaging procedures and Part III, Nursing, embodies the elements of patient care, administration of medicines, and hygiene. A thorough knowledge of the contents of this book will enable you to satisfactorily demonstrate the required knowledge for advancement to Hospitalman (HN).

MISSION OF THE NAVY

The primary mission of our Navy is to maintain control of the seas for ourselves and our allies, and to deny the use of the sea areas to our enemies. Why is this assignment so important? The reason is that some 78 percent of the raw materials that this country needs to survive are transported to this country by sea. If we lose control of the sea and our imports are cut off, we cannot survive.

In days past, the armed sailing ship—the dreadnought—and a strong maritime fleet were the means of achieving this control, which has come to be known universally as sea power.

Today, the elements that make up sea power are diverse and numerous. These elements are the combatant ships and naval air arm, together with the various auxiliary craft, the Marine Corps, and the merchant marine. Thus, it can be seen that the need for and objectives of sea power remain unchanged, but the particular elements composing it have changed.

Our Navy of tomorrow may not be a navy of guided missile cruisers, nuclear-powered submarines, and supercarriers launching supersonic fighters and bombers. Yet, it will certainly be a navy in the best sense—a mobile organization using ocean highways, carrying its own defense against any weapon directed against it by an enemy, and launching from its mobile platform whatever the naval engineers of today and tomorrow may adapt or devise (rockets, guided missiles, nuclear bombs, and so forth).

This certainly, however, should be borne in mind: Although fleets change, the need for sea power always remains. And the Navy of today and tomorrow can be depended on at all times to fulfill this need.

RATING STRUCTURE

The training mission of the peacetime Navy is to produce broadly qualified, versatile personnel who, particularly in time of emergency, can be advanced to positions of greater responsibility and authority. If this mission is to be accomplished, several jobs have to be performed. These jobs have been classified in accordance with the rating structure.

10218

In order to understand the rating structure, which provides for the Navy's needs under both peacetime and wartime conditions, you must understand the difference between a rating and a rate.

An occupational group of jobs requiring similar interests, training, experience, knowledge, and skills is known as a rating.

Within every rating are steps for advancement, and with each step there is an increase in pay. These steps, or pay grades, are the rates within the rating. The rating in this illustrative case is Hospital Corpsman, abbreviated HM. The rates are Hospital Corpsman Third, Hospital Corpsman Second, Hospital Corpsman First, Chief Hospital Corpsman, Senior Chief Hospital Corpsman, and Master Chief Hospital Corpsman, abbreviated HM3, HM2, HM1, HMC, HMCS, and HMCM. In the same manner, Hospitalman, Hospital Apprentice, and Hospital Recruit are rates, because they also denote levels within occupational areas.

QUALS MANUAL

One of the most important publications relating to any enlisted man's career is the Manual of Qualifications for Advancement in Rating, NavPers 18068B, known throughout the Navy as the Quals Manual. Military and professional requirements for advancing to Hospitalman (and all other rates and ratings) are contained in the Quals Manual. The qualifications for Hospitalman form the basis for this course, and they were current at the date of this printing. But the qualifications change occasionally, and the questions in the advancement examinations for all pay grades are based on the latest revision. Consequently, well before taking an examination for advancement to Hospitalman, you should check for revisions and assure yourself that your knowledge covers all the latest qualifications.

ADVANCEMENT

Before you can advance in rate, you must fulfill certain military and professional requirements.

MILITARY REQUIREMENTS

Military requirements for advancement are those general qualifications applicable to all enlisted personnel, such as watch standing, first aid, and military conduct. These requirements are published in the Quals Manual, near the front, preceding the professional qualifications. Before you can advance, you must show that you are proficient in each of the military qualifications specified for the next higher pay grade. You also may be required to demonstrate your proficiency in the military quals for all the lower pay grades. These are covered in Basic Military Requirements, NavPers 10054-B.

PROFESSIONAL REQUIREMENTS

Professional qualifications are the ones a Navy enlisted man must have to qualify for a rate (apprenticeship, third, second, first, or chief) within a particular rating (Hospital Corpsman, Quartermaster, etc.). The higher the rate, the more the man is required to know.

The qualifications are further divided into practical factors and knowledge factors. Practical factors are qualifications that can be demonstrated best by performance.

A special checkoff sheet, titled Record of Practical Factors, NavPers 760, lists all the practical factors shown in the Quals Manual for the rate to which you are advancing. It is kept by your supervisor or division officer; you are given a duplicate copy. As you qualify in a practical factor, your supervisor or division officer enters the date and initials the entry. When you are transferred, the checkoff sheet accompanies your record to the next duty station.

Before you can take the servicewide examination, there must be an entry in your service record to prove that you are qualified in the practical factors. The servicewide examination is based on (1) a thorough knowledge of the manner in which the practical factors are performed, and (2) the qualifications listed under the knowledge factors. An example of a knowledge factor is the "qual" that requires you to know the meaning and significance of certain Rules of the Road.

HOW TO ADVANCE

The Navy has established certain requirements that must be met before you are eligible to take the servicewide competitive examination for advancement in rate or rating. You must—

First: Meet basic requirements, such as length of service in pay grade, total service, and sea duty time.

Second: Have a statement in your service record that you satisfactorily performed the practical factors for the next higher rate.

10219

Third: Have a statement in your service record that you successfully completed the training course for the next higher rate.

Fourth: Be recommended by your commanding officer.

When you satisfy all of these requirements, you are eligible to participate in the examination. If you pass the examination with a high enough score, your commanding officer has the authority to advance you in rating.

REWARDS OF ADVANCEMENT

Each time you advance in your rating, you receive many rewards. These rewards include higher pay and allowances, together with additional pension benefits when you retire. But the really important gains are opportunities for more interesting and challenging assignments, increased respect from your superiors as well as from the men you supervise or help, and the chance for greater fulfillment of your abilities. Above all, you are afforded the opportunity to serve your command, your Navy, and your country at a higher level of responsibility in a more important job.

As a member of the greatest Navy in the world, you have the satisfaction of knowing that, as you advance in a rating, you are serving your country in a most important way. Do your job well at all times, and take pride in what you do and how you do it. Service to your country is a special privilege. You must make every endeavor to serve with honor.

Tradition, valor, and victory are the Navy's heritage. The long history of outstanding achievements and noble service of the Navy provides an inspiration and a challenge to you and your shipmates. It is up to you to help maintain and enlarge the prestige and the traditions of the naval service.

NAVPERS 10052

The Navy has set definite limits on the material for which you are accountable on servicewide examinations. The sources from which examination items are taken are listed in the effective edition of a pamphlet called Training Publication for Advancement in Rating, NavPers 10052. This pamphlet is available on your ship or station. It is revised annually, so be sure to consult the current edition. This pamphlet provides the titles of publications and sections of publications that you should study when preparing for the examination. The publications listed contain material covering all the qualifications as shown in the Quals Manual.

Get to know NavPers 10052. After you read the instructions, only two sections are of further interest to you. One section contains the sources you should study to meet the military requirements for advancement. The other lists sources for study to qualify in a specified rating. An asterisk (*) marks the Navy Training Courses you must complete before you can be eligible for servicewide examination for advancement.

LEADERSHIP

As a Hospitalman, the occasions on which you will be able to display your leadership qualities may be very limited. You will be expected to show a continued willingness to undertake any task assigned by your immediate supervisors and to perform it cheerfully and efficiently.

This period of being a follower rather than a leader should be one of valuable training for your future responsibility of leadership. Because they will be advantageous when you are placed in a responsible position over other men, you should develop these leadership factors now: (1) know your job; (2) know the men you work with; and (3) always set a good example.

A man who aspires to be a good leader must know his job. Lack of such knowledge can result only in poor leadership. You should try constantly to improve your knowledge of your specialty and the organization of the Navy.

Knowing the men you work with is also a must. Get to know the capabilities and limitations of the men you work with. This knowledge of men will help you when the time comes to organize them successfully into an efficient working unit.

Finally, set an example that will measure up to the expected Navy standards. There are many ways in which a good example may be set. Some of these are obvious—smart military appearance, exemplary conduct, obedience to rules and regulations, even temperament, loyalty to superiors and subordinates, clean speech and a willingness to share danger and hardship. Other good points, such as moral courage and self-confidence, should be present in every action you perform. All these influences are important, but the degree to which you measure up to them will determine the type of example you set for the men around you.

10220 ISSUE

PROFESSIONAL ETHICS

Professional ethics refers to the adherence to moral principles by members of a profession in the practice of that profession. As a hospital corpsman, you must learn and ahere to a code of behavior which is based on sound moral beliefs and which is so ingrained as to become a way of life. Your responsibility as a hospital corpsman to exhibit ethical behavior is in three major areas:

YOUR FIRST RESPONSIBILITY IS TO YOUR PATIENT

You must always recognize your obligation to give the best care that you are capable of giving to every patient committed to your charge. This care must reflect a belief in the worth and dignity of every patient as a human being. Courteous, efficient, and conscientious service is the mark of an outstanding corpsman. Respect for the patient's right to privacy must be honored and particularly when he discloses privileged information to you. This should never be repeated to any unauthorized person. Your patient's welfare is paramount.

YOUR SECOND RESPONSIBILITY IS TO THE TEAM

Doctors, nurses, and hospital corpsmen comprise the team dedicated to healing the patient. Mutual respect and understanding of the role and the person of each member is of vital importance to the success of the team. Cooperation of all the members is essential. The doctor, as team leader, carries the overall responsibility for the welfare of the patient. He prescribes the medical treatment and oversees the total care of all patients. The nurse is responsible for meeting the nursing needs of the patient and insuring that all of the doctor's orders and nursing measures are carried out accurately. Both the doctor and nurse are responsible for instructing the hospital corpsman in the performance of his duties.

The hospital corpsman is responsible for carrying out the doctor's and nurse's orders and giving nursing care to patients.

YOUR THIRD RESPONSIBILITY IS TO THE HOSPITAL CORPS

The heritage of the Hospital Corps places a special burden on every new member. He is responsible for upholding its proud tradition. The tradition of "service with distinction" has been established by your predecessors in every corner of the world and under every kind of adversity.

Your patient, the members of the team you serve, and your shipmates deserve your respect and cooperation. They merit your confidence. Respect and confidence coupled with your skill will allow you to carry on in the proud tradition of the Hospital Corps.

Professional ethics is the key to service with distinction.

TRAINING AIDS

There are many good films, both movie and strip, available to assist in the group-training of Hospital Corpsmen. The best source of information for such films and their method of procurement for an organization such as a Naval Reserve Unit where group study of this text is used, is the current edition of "Film Reference Guide for Medicine and Allied Sciences", NavMed P5052.

10221 10220

CHAPTER 1

INTRODUCTION TO HUMAN ANATOMY

STUDY OF THE HUMAN BODY

The human body is a combination of organ systems with a supporting framework of muscles, bones, and an external covering of skin. The smallest unit of life, the cell, is the building block of which all these organs and systems are made. The study of the body is divided into divisions which may be defined as follows:

1. HUMAN ANATOMY.—The study of body structure and the relation of one part to another. Specifically it is further subdivided into:

a. Descriptive anatomy, the word picture of the character, form, and size of the various parts of the body.

b. Surgical anatomy dealing with special features of those portions of the body that are important in the diagnosis and treatment of surgical diseases.

c. Topographic anatomy, the study of the relationship of the parts of the body to surrounding parts.

d. Surface anatomy concerning the form and markings on the surface of the body. It helps in locating, on a patient, such parts as nerves or bones which are hidden by the skin.

2. HUMAN PHYSIOLOGY.—The study of the body's functions and activities. How the body works—showing what the individual parts do in relation to one another and as a unit (how the heart acts by itself and as a part of the body).

3. EMBRYOLOGY.—The study of the development of the body from a fertilized egg or ovum.

CLASSIFICATION OF LIVING MATTER

Everything in nature is either animal, vegetable, or mineral. Minerals are void of life and are known as inorganic matter. Animals and vegetables possess life and are known as organic matter. This means that they have been made up by matter that has been organized by life processes.

Any living thing, plant or animal, is an organism. The difference between them is that animals have sensation and the power of voluntary movement, and require oxygen and organic food. Plants require only carbon dioxide and inorganic matter for food, and have neither voluntary movement nor special sensory organs.

Plants and animals are symbiotic. Living side by side they sustain each other by their life cycle. Animals need oxygen which the plants give off, and they require plants for food in order to obtain protein, carbohydrates, and fats for building body cells. They exhale carbon dioxide and give off wastes which are in turn used by the plants.

The manner in which plants manufacture proteins, carbohydrates, and fats is interesting. These organic compounds are formed by the action of the sun's rays upon the leaf's green chlorophyll. This action unites the air's carbon dioxide with the mineral salt solution from the soil freeing oxygen to the air in the form of water vapor. This process is called photosynthesis.

Animals eat food containing organic matter and after digesting and absorbing it, either convert it into body cells or burn it with the aid of oxygen inhaled into the lungs to produce energy. As the waste products are formed, some are excreted by the bowels and kidneys while others, mainly carbon dioxide, are exhaled from the lungs.

Animals are classified into many divisions. Those with a backbone, including fishes, reptiles, birds, and mammalia, are called vertebrates. Those without backbone are called invertebrates. Man belongs to the class or division called mammalia (those that suckle their young).

10222

He is unique in having the power of articulate speech and the ability to reason abstractly.

CHARACTERISTICS OF LIVING MATTER

All animal and plant life have certain chemical processes by which life is sustained and cells regenerated. These processes, from the time the food enters the body until it is made into tissues to repair the body, or is burned to provide energy, are metabolic. Metabolism involves the absorption, storage and use of food for growth and body repair. It also involves the combination of food with oxygen to make energy, and the final elimination of waste materials. It is the burning of foods that supplies the energy for carrying on all body processes. This food burning also maintains body temperature in warm blooded animals.

Another characteristic of living matter is its irritability or excitability. It responds to stimulation. Even a one-celled animal will move away when stuck with a pin, and you are all familiar with how you respond when this happens to you. The action which takes place is similar to that of a telephone call. You dial a number and an impulse is sent through the line to a central control where it is relayed to the proper party. When you receive a pin-prick the skin relays by way of the central nervous system to the brain that something is wrong. The system in turn activates another nerve or set of nerves causing contraction or withdrawal of the part. This is an example of irritability.

THE CELL

All living cells are composed of a viscid, jelly-like substance called protoplasm. Upon it depend all the vital functions of nutrition, secretion, growth, circulation, reproduction, excitability, and movement. The secret of life itself is actually contained in protoplasm.

As the atom is the basic unit of any element, the cell is the basic unit of any living organism. It is the building block of the body. Cells vary in size from the rickettsia (about 0.5 millimicron) to the ostrich egg (about 3 inches or about 15 million times the size of the rickettsia).

A typical cell is made up of a cell wall, cytoplasm, nucleus, and a nucleolus.

The simplest living organism consists of a single cell (yeast and bacteria are one-celled plants; the ameba is a one-celled animal). The single cell of such a one-celled organism must be able to carry on all processes necessary for life. That is they must be able to be stimulated, have movement, eat, grow, and reproduce. This type of cell is called a simple or undifferentiated cell.

In the multicellular organisms, cells vary in size, shape and number of nuclei. When stained, the various types of structures can be more readily recognized under a microscope. Other differences such as the number and type of cells can be seen with the aid of a microscope. Many cells are highly specialized. Specialized cells are those that perform a special function such as muscle which contracts or epithelial cells of the skin which protect.

An important structural feature of body cells is the permeable cell wall through which fluids may pass. This is of importance because all body cells are bathed in tissue fluid from which nourishment, essential to life and growth, is received. From the tissue fluids, they absorb oxygen, proteins, carbohydrates, mineral salts and water. This absorption is accomplished by diffusing these substances from the blood stream to the body cells through the permeable membranes of the body tissues and capillaries.

Cells may be excited to activity by mechanical, chemical or nervous stimulation. This produces muscular movement, or secretions such as the digestive juices of the stomach and the increase of hormones such as adrenalin secreted in anger or fear. The stimuli are carried to the cells by nerves or are caused by chemical substances that reach the cell through blood and tissue fluid.

TISSUES

Tissues are groups of specialized cells similar in structure and function. They are classified in five main groups:

1. EPITHELIAL.—The lining tissue of the body. It forms the outer covering of the body known as the free surface of the skin. It also forms the lining of the digestive, respiratory, and urinary tracts, the blood and lymph vessels, serous cavities, and tubules of such secretory glands as the liver and kidneys. This tissue may be further subdivided into three types:

a. Columnar.—The chief function of this tissue is the secretion of digestive fluids and the absorption of digested foods and fluids. It consists of long narrow cells set close together resembling a palisade type fence. (See fig. 1-1.) In certain areas such as nose, bronchial tubes, and trachea, this tissue has a crown of microscopic hair-like processes known as cilia. These

10223

cilia provide motion to move secretions and other matter along the surfaces from which they extend. They also act as a barrier—preventing foreign matter from entering into these cavities.

Figure 1-1.—Columnar epithelial tissue.

b. Squamous.—This is the main protective tissue of the body. It is composed of thin plate or scale-like cells forming a mosaic pattern. This tissue is found in the tympanic membrane of the ear (ear drum) as a single layer of cells or in the free skin surface in multiple layers. (See fig. 1-2.)

Figure 1-2.—Squamous epithelial tissue.

c. Cuboidal.—This tissue is both a secretory and protective tissue whose shape is similar to a cube. It is found in the more highly specialized organs of the body such as the ovary and kidney. (See fig. 1-3.)

Figure 1-3.—Cuboidal epithelial tissue.

2. CONNECTIVE.—The supporting tissue of the body. This tissue with its many variations, is the most widespread tissue of the body and is highly vascular. It surrounds cells, encases internal organs, sheathes muscles, wraps bones, encloses joints, composes blood and provides the supporting framework of the body structure. Structures of connective tissue differ widely. They range from delicate tissue-paper membranes, strong tough cords, and rigid bones to liquid blood and are all made of connective tissue.

Connective tissue is composed of few cells and large amounts of intracellular material; the reverse is true of epithelial tissue.

Some of the more predominant types of connective tissues are:

a. Areolar.—This serves to connect the various tissues of the organs. It is continuous through the body. Nerves, blood and lymph vessels are found in this tissue. (See fig. 1-4.)

Figure 1-4.—Areolar connective tissue.

b. Adipose.—This is generally called "fatty tissue". It acts as a reservoir for energy producing foods, helps to reduce body heat loss (because of its poor heat conductivity) and serves as support for various organs and fragile structures such as the kidneys, blood vessels, and nerves.

c. Osseous.—Cartilage and fibrous tissue are the least vascular of the connective tissues. They form the supporting framework of the body. (See fig. 1-5.)

Figure 1-5.—Osseous (bone) tissue.

10224

(A) PICTORIAL DIAGRAM

(B) EQUIVALENT CIRCUIT

Figure 12-36.—Balanced mixer employing hybrid junctions.

Details of connections of the IF amplifier input circuit, together with the ideal transformer equivalent circuit of the waveguide junction are given in the right-hand block of (B). The parallel circuit comprising L, C, and R is tuned to the intermediate frequency and the impedance of the parallel combination of L′, C′, and R′ is made equal to the conjugate of the IF impedance appearing between the terminals to which L′, C′, and R′ are connected.

Ideally the two crystals should be alike. Furthermore, all RF impedances should terminate the entries of the RF hybrid junction in matched loads, and all IF impedances should similarly terminate the entries of the IF hybrid junction. Then, because of the properties of

3. MUSCULAR.—The tissue which provides all body movement. It is classified into two types:

a. Voluntary muscle fibers are striated or striped. This type is subject to the control of the individual's will or thought. (See fig. 1-6.)

Figure 1-6.—Striated muscle.

b. Involuntary muscle fibers are smooth or non-striated. This type operates involuntarily or automatically and is not subject to the individual's will. The beating of the heart is an example of involuntary muscle action. (See fig. 1-7.)

Figure 1-7.—Non-striated muscle.

Structurally speaking the skeletal muscles are voluntary and the visceral muscles are involuntary. The exception to this classification is the heart. It is an involuntary, faintly striated muscle and is called the CARDIAC MUSCLE. (See fig. 1-8.)

4. LIQUID TISSUES.—These tissues act as a medium for supplying the body with nutrients and as a vehicle for elimination of waste materials. They form the blood, lymph, and tissue fluids.

5. NERVOUS TISSUE.—This tissue is the most complex tissue of the body. It is the

Figure 1-8.—Cardiac muscle.

Figure 1-9.—Anatomical planes and postures.

10225

substance of the brain, spinal cord, and nerves. Nervous tissue requires oxygen and nutrition to a higher degree than any other body tissue.

In the body, cells are the smallest building blocks. Groups of cells form tissues, and similar tissues form organs such as the heart, liver, and kidneys. These organs are grouped together to form systems such as the urinary system, which is composed of the kidneys, ureters, bladder, and urethra.

ANATOMICAL TERMS

To assist in describing the body, certain anatomical terms are used. For determining position and direction you should be familiar with the anatomical position of the body.

THE ANATOMICAL POSITION.—The arms hang to the sides, palms of the hands facing forward or to the front, and the body in an upright or erect standing position.

The terms of reference which indicate direction and position are:

1. Anterior—toward the front or ventral (pertaining to the belly; abdomen) side of the body.
2. Posterior—toward the back or dorsal side of the body.
3. Medial—near or toward the midline of the body.
4. Lateral—farther from the midline of the body.
5. Internal—inside.
6. External—outside.
7. Proximal—nearer the point of origin or closer to the body.
8. Distal—away from the point of origin or away from the body.
9. Superior—higher than or above.
10. Cranial—toward the head.
11. Caudal—toward the lower end of the body.
12. Inferior—lower than or below.
13. Erect—normal standing position of the body, palms of hands to the front.
14. Supine—lying position of the body, face up.
15. Prone—lying position of the body, face down.
16. Lateral recumbent—lying position of the body, on either right or left side.
17. Periphery—the outside or surface of a body organ.

10226

CHAPTER 2

OSTEOLOGY

SKELETON

The skeleton is the bony framework of the body. (See fig. 2-2.) This framework supports and gives shape to the body, protects vital organs, and affords attachments for tendons, muscles and ligaments. The skeletal bones are joined members by which muscle movement is made possible.

BONES

OSTEOLOGY is the study of the structure of bone. Bone is made up of calcium, phosphorus, and other mineral salts, and an organic substance called ossein. When human bone is soaked in dilute acid until all inorganic mineral salts are washed out, all that remains is a flexible piece of tissue which can be bent and twisted easily. Bone, therefore, depends upon inorganic mineral salts such as calcium and phosphorus for its strength and hardness. From this, we can see that bone is both hard and elastic. Two-thirds of the bone is mineral matter (lime salts) which gives it hardness; the remaining one-third is organic matter containing protein which gives it elasticity. The degree of elasticity decreases with age. Children's bones which are greatly elastic, do not break as easily as an adult's because they do not have the mineral content that increases with age.

Bone structure consists of a hard outer shell, called the compact tissue, and an inner spongy, porous center called the cancellous tissue. (See fig. 2-1.) The center of the bone is called the Medullary canal and contains marrow. There are two types of marrow, red and yellow. Yellow marrow is ordinary bone marrow in which fat cells predominate. It is found in the medullary canals and cancellous tissue of long bones. Red marrow is one of the manufacturing centers of red blood cells and is found in the articular ends of the long bones, and in cancellous tissue. At the ends of the long bones there is a smooth, glossy tissue which forms the joint surfaces. This tissue is called articular cartilage because these surfaces articulate (join) with, fit into, or move in contact with, similar surfaces of other bones. The thin outer membrane which surrounds the bone is called the PERIOSTEUM. An important function of the periosteum is to supply nourishment to the bone. Capillaries and blood vessels run through (course) the periosteum and dip into the bone surface supplying it with blood and nourishment. The periosteum is the pain center of the bone. When there is a fracture, the pain you feel comes from the periosteum, not the bone proper. Periosteum also forms new bone.

CLASSIFICATION.—Bones are classified according to shape, as:

1. Long—the femur and humerus.
2. Short—the wrist and ankle bones.
3. Flat—the skull, sternum and scapula.
4. Irregular—the vertebrae, mandible, hyoid and pelvic bones.

NUMBER OF BONES.—There are 206 named bones in the adult skeleton.

Cranium	8
Face	14
Ear	6
Hyoid	1
Spine Vertebral Column) (True Vertebrae	24
Sacrum and Coccyx	2
Ribs and Sternum	25
Upper Extremities	64
Lower Extremities	62

THE SKULL

Encasing the brain is a bony framework called the skull. It is divided into two parts, the cranium

10227

Figure 2-1—Structure of a typical long bone.

and the face. It is made up of 22 bones, 8 of which form the cranium and 14 the face.

CRANIAL BONES.—(See figs. 2-3 and 2-4.) These bones are firmly united and fit snugly together. The lines formed by the interlocking of adjacent bones are called sutures. The most important of these are the sagittal, coronal, and lamboidal sutures. The skull is formed by 8 cranial bones; 6 are essential to know. The frontal bone which forms the forehead, contains the frontal sinuses and helps to form the eye-socket and nasal cavity. The two parietal bones form the roof of the skull. The two temporal bones which help form the sides and base of the skull, also house the auditory or hearing organs. The occipital bone forms the base or back of the skull and has a large hole in it called foramen magnum. This opening permits passage of the spinal cord from the cranium into the spinal column.

FACIAL BONES.—(See fig. 2-4.) The two maxillary bones form the upper jaw, nasal walls, and part of the eyesocket. These bones contain large cavities called maxillary sinuses. Frequently these sinuses become infected causing the individual much discomfort. The lower jaw is called the mandible, and its main function is mastication. It is the only moveable bone in the skull. Other bones of the face are the lacrimal and nasal bones.

Figure 2-2.—The human skeleton.

10228

Figure 2-3.—Skull, posterior lateral view.

Figure 2-4.—Skull, frontal view.

THE VERTEBRAL COLUMN

The vertebral or spinal column consists of 24 moveable or true vertebrae, the sacrum, and the coccyx or tail bone. (See fig. 2-5.) The vertebrae are divided into five regions:

1. Cervical or neck.
2. Thoracic or chest.
3. Lumbar or lower back.
4. Sacral.
5. Coccygeal.

The vertebrae are designed to serve as a bony protection for the spinal cord, and the nerves which arise from the spinal cord. Each vertebra, bat-like in construction, has a solid segment of bone in front. (See fig. 2-6.) The vertebral column supports not only the spinal cord, but other organs as well. Many of the main muscles are also attached to the vertebrae. The vertebral foramen is a hole directly behind the body of the vertebrae and forms the passage for the spinal cord. The projecting side of the vertebrae with its various projections and facets are for the attachment of spinal muscles, and to facilitate movement of one vertebra over another.

There are 7 cervical vertebrae in the neck. The first is called the atlas because it supports the head. The second is called the axis, as the head turns upon it. These are the only named vertebrae, all others are numbered. Each cervical vertebra has a transverse foramen to allow passage of nerves, vertebral artery, and a vein. The seventh cervical vertebra has an especially prominent projection which can easily be felt at the nape of the neck. This makes it possible for doctors to count and identify the vertebrae above and below it.

There are twelve vertebrae in the thoracic region. These articulate with the posterior portion of the twelve ribs to form the posterior wall of the thoracic or chest cage. There are five lumbar vertebrae. The vertebrae in this region are the heaviest and broadest of the vertebral column.

The sacrum is roughly triangular in shape and is formed by the fusion of five false vertebrae. The sacrum articulates on each side with the hip bone and with the coccyx to form the posterior wall of the pelvis.

Figure 2-5.—The vertebral column.

10229

Figure 2-6.—Typical vertebra.

THE THORAX

The thorax is a cone-shaped bony cage, about as wide as it is deep. (See fig. 2-7.) It is formed by 12 ribs on each side which articulate posteriorly with the thoracic vertebrae; 10 of them articulate anteriorly with articulating cartilage and the sternum. It houses the heart and lungs, the vital organs of respiration and circulation.

The sternum occupies the middle of the upper half of the chest wall in front. It is attached to the clavicles and the cartilages of the first seven ribs.

Figure 2-7.—Thorax, anterior view.

There are twelve pairs of ribs which form a series of curved bones to support the chest wall. The first seven ribs attached to the sternum are called true ribs. The eighth, ninth and tenth ribs are united by their cartilages to the cartilage of the seventh rib and are called false ribs. The last two ribs are free or unattached in front and are called floating ribs.

UPPER EXTREMITIES

The upper extremity consists of the shoulder, the arm, the forearm, the wrist and the hand. The bones that form the framework for the upper extremity are:

1. Clavicle	collar bone	2
2. Scapula	shoulder blade	2
3. Humerus	arm bone	2
4. Radius and ulna	forearm bones	4
5. Carpus	wrist bones	16
6. Metacarpus	bones of the palm	10
7. Phalanges	finger bones	28

CLAVICLE.—The clavicle forms the front part of the shoulder girdle. (See fig. 2-8.) It lies in a horizontal position just above the first

Figure 2-8.—The shoulder girdle—exploded view.

rib and is shaped like a flat letter "S". Because of its poor protection and location, the clavicle is often fractured as a result of falls. Its inner end is round and is attached to the sternum. Its outer end is flattened and is fixed to the scapula.

SCAPULA.—The scapula is a triangular shaped bone which lies in the upper part of the back on both sides between the second and seventh ribs, and forms the posterior portion of the shoulder girdle. Its lateral corner forms part of the shoulder joint, articulating with the humerus (See fig. 2-8.)

HUMERUS.—The humerus is the longest bone of the upper extremity and is often called the arm bone. (See fig. 2-8.) It articulates with the shoulder girdle to form the shoulder joint, and the bones of the forearm to form the elbow. The anatomic portions include the head, a rounded portion which fits into a recess of the scapula called the glenoid fossa (or cavity); the greater and lesser tuberosities which are enlargements of the proximal end; a surgical neck which is a slight narrowing below the tuberosities and a frequent site of fractures; the shaft which is the main part of the humerus; and the distal end which includes the prominences called espcondyles and the surfaces which articulate with the forearm bones.

RADIUS AND ULNA.—When the arm is in anatomic position, the palm facing forward, the radius is on the lateral or thumb side and the ulna in on the medial or little finger side. When the hand is pronated (palm down), the bones rotate on each other and cross in the middle. This makes it possible to turn the wrist and hand as in opening doors. The ulna and radius articulate at their proximal ends with the humerus, at their distal ends with some of the carpal bones, and with each other at both ends. (See fig. 2-9.)

CARPUS.—There are eight carpal bones arranged in two rows forming the wrist. (See fig. 2-9.)

METACARPUS.—The metacarpal bones are numbered one to five corresponding with the five fingers or digits and the phalanges with which they articulate. (See fig. 2-9.) The fingers are named as follows:

1st—thumb; 2nd—index; 3rd—middle; 4th—ring; and 5th—little.

Figure 2-9.—The forearm and hand.

PHALANGES.—These are the small bones of the fingers. Each finger has three bones except the thumb, which has two. The bone at the end of the finger is called distal phalanx. The one closest to the hand is called the proximal phalanx, while the one in between is called the middle phalanx. (See fig. 2-9.)

LOWER EXTREMITIES

The lower extremity includes the foot, ankle, leg, thigh, and hip. The bones that form the framework of the lower extremities are:

1. Innominate . . . . hip bone 2
2. Femur. . . . . thigh bone 2
3. Patella . . . . . knee cap 2
4. Tibia. . . . . leg bones 2
5. Fibula . . . . . leg bones 2

10231

10230

6. Tarsus . . . . . ankle bones 14
7. Metatarsus . . . foot bones 10
8. Phalanges . . . . toe bones 28

INNOMINATE.—The hip or innominate bone is a large irregularly shaped bone composed of three parts, the ilium, ischium and pubis. (See fig. 2-10.) In children, these three parts are separate bones which become firmly united into one bone to form a cup-like structure called the acetabulum, into which the head of the femur fits. The ilium forms the outer prominence of the hip bone (crest of the ilium), the ischium forms the hard lower part and the pubis forms the front part of the pelvis. (See fig. 2-11.)

The area where the two pubis bones meet is called the symphysis pubis and is often used in anatomical measurements. The largest foramen is located in the hip bone between the ischium and pubis and is called the obturator foramen. The crest of the ilium is used in making anatomical and surgical measurements (i.e., location of the appendix which lies approximately midway between the crest of the ilium and the umbilicus).

FEMUR.—The femur or thigh bone is the longest bone in the body. The proximal end is rounded and has a head supported by a constricted neck which fits into the acetabulum. There are two processes at the proximal end for the attachment of muscles called the greater and lesser trochanters. The neck of the femur located between the head and trochanters is the site most frequently fractured. At the distal

Figure 2-10.—The innominate bone—lateral view.

Figure 2-11.—The pelvic girdle.

end are two bony prominences called the lateral and medial condyles. These articulate with the tibia and patella. (See fig. 2-12.)

PATELLA.—This is a small flat, triangular sesamoid bone overlying the knee joint. It is enclosed within the tendon of the quadriceps muscle of the thigh (sesamoid—a small flat bone which develops within a tendon).

TIBIA.—The tibia or shinbone is the larger of the two leg bones and lies at the front and medial side. The proximal end articulates with the femur and fibula. Its distal end articulates with the talus (one of the foot bones) and the fibula. A prominence easily felt on the inner aspect of the ankle is called the medial malleolus. (See fig. 2-12.)

FIBULA.—The fibula, the smaller of the two leg bones, is located on the lateral side of the leg parallel to the tibia. The prominence at the distal end forms the outer ankle known as the lateral malleolus. (See fig. 2-12.)

TARSUS.—The ankle is formed by seven tarsal bones. The strongest of these is the calcaneus or heel bone. The heel bone transmits the body's weight to the grand and acts as a lever for the muscles of the calf. (See fig. 2-12.)

METATARSUS.—The sole and instep of the foot is made up of five metatarsals. They are similar in arrangement to the metacarpals of the hand.

10232

Figure 2-12.—The bones of the lower extremity.

PHALANGES.—These are the bones of the toes and are similiar in number, structure, and arrangement to those in the fingers.

JOINTS

GENERAL.—Arthrology is the study of joints or articulations. Wherever two bones are attached to each other, a joint is formed. In a freely movable joint such as the knee or elbow joint, the ends of the bones are covered with a smooth layer of cartilage. The whole joint is enclosed in a watertight sac or membrane, containing a small amount of lubricating fluid. This enables the joint to work with little friction. The function of the ligaments which reach across the joints from one bone to another keeps them from getting out of place. When ligaments are accidentally torn, we call the injury a sprain; when bones get out of place, there is a dislocation. When bones are chipped or broken, the injury is called a fracture.

Joints are classified according to the type of motion they produce. These types are:

1. IMMOVABLE.—Bones of the skull which are rigidly interlocked along lines called sutures.

2. SLIGHTLY MOVABLE.—Bones of the vertebrae and symphysis pubis, where the bones are held together by broad flattened discs of cartilage and ligaments.

3. FREELY MOVABLE.—Such joints as the knee, hip and shoulder. These joints are further subdivided into:

a. hinge joints . . . . . elbow and knee
b. ball and socket. . . shoulder and hip

10233

Figure 2-13.—Typical joints.

c. gliding . . . . . wrist and ankle
d. pivot or rotary. . axis rotation about the atlas

JOINT MOVEMENTS.—These movements may be divided into four types:

1. GLIDING is the simplest type of motion. It is one surface moving over another without any rotary or angular motion. This motion exists between any two contiguous or adjacent surfaces.

2. ANGULAR motion decreases or increases the angle between two adjoining bones. The more common types of angular motion are:

a. Flexion.—Bending of the arm or the leg.
b. Extension.—Straightening or unbending, as in straightening the forearm, leg or fingers.
c. Abduction.—Moving an extremity away from the body, as in abducting the arm.
d. Adduction.—Bringing an extremity towards the body, as in adducting the arm.

3. ROTATION is a movement where the bone moves around a central point without being displaced.

4. CIRCUMDUCTION is the movement of hips and shoulders.

Other types of movement include the following, which are generally used to indicate specific anatomical positions.

1. Supination—Turning upward as in placing the hand palm up.

2. Pronation—Turning downward as in placing the hand palm down.

3. Eversion—Turning outward, as in turning the sole of the foot to the outside.

4. Inversion—Turning inward, as in turning the sole of the foot inward.

10234

a matched hybrid junction, local oscillator signals at the crystals are equal in amplitude and in phase, and echo signals at the crystals are equal amplitude and 180° apart in phase.

The IF components of signals from the crystals are applied in push-pull to ideal transformer T3 and appear across L, C, and R but not across L′, C′, and R′. The IF components of noise, on the other hand, are in effect applied between end terminals of T3 in parallel and appear across L′, C′, and R′, but not across the IF output terminals. Local oscillator noise is thus suppressed completely. Because the RF hybrid junction is matched, the total available power from the echo signal and local oscillator arms divides equally between the two crystals. As in the coaxial line line mixer of figure 12-35, the IF power from each crystal is one-half the available echo signal power times the conversion gain G of the crystal. Since IF power from each crystal is delivered at the IF output terminal, the total IF output is the product of the echo signal power and G, as before.

Ordinarily, in single-ended mixers and in the coaxial line balanced mixer (fig. 12-35), the local oscillator must be loosely coupled to the mixer in order to prevent an appreciable amount of echo signal power from entering the local oscillator circuit. As a result, the local oscillator must generate much more power than is actually needed for mixer operation, the excess power being dissipated in an impedance changing device located in the local oscillator circuit. Because in a hybrid junction mixer the echo signal and local oscillator arms are decoupled, there is no tendency for echo signals to enter the local oscillator circuit, and hence there is no need for loose coupling between local oscillator and mixer. A local oscillator with relatively low power output can therefore be used, the only power necessary being that which is needed to drive the crystals. Actually most local oscillators are capable of generating more than the minimum power required, so that a dissipative attenuator can be inserted in the local oscillator in order to insure a matched termination for the arm. Such an attenuator is desirable, as will be seen later.

Decoupling between echo signal and local oscillator arms also means that there is no tendency for local oscillator power to enter the echo signal arm. Rejection of local oscillator signal by the echo signal arm is particularly advantageous in systems employing a broadband TR device which would allow local oscillator power to pass through and be radiated by the antenna.

Another advantage of the hybrid junction mixer is that its operation is less sensitive to differences in the RF impedance of the crystals than is the balanced coaxial line mixer. Because the two crystal arms are decoupled, any RF power reflected from one crystal cannot reach the other crystal. All the reflected power is directed into the echo signal and local oscillator arms and absorbed by the matched terminations. Thus the amount of RF power delivered to one crystal is independent of the RF impedance of the other.

If a mismatch should exist in either the echo signal or local oscillator arm, a reflection of an RF signal arriving at the mismatched termination will occur, and the signal reflected from the termination will enter the two crystal arms. Under these circumstances, the two crystal arms are not completely decoupled. At the echo signal frequency a mismatch in the echo signal and local oscillator arms is unlikely because in general the TR device provides a matched load for the echo signal arm and, as indicated above, a matching attenuator can normally be inserted in the local oscillator arm.

In general, if the crystals provide an impedance match at the echo signal frequency, they do not yield a perfect match at the local oscillator frequency. This mismatch is unimportant, since the reflected power will be absorbed in the echo signal and local oscillator arms. The attenuator in the latter arm serves to prevent the returned signal from reacting on the oscillator. Should the echo signal arm not provide a matched termination for the returned local oscillator signal, further reflection of the signal will occur and the balance of local oscillator power at the crystals will be further upset. The effect of such an imbalance is to change the conversion gains of the crystals slightly, but usually the change is negligible even with moderate amounts of mismatch at the local oscillator frequency.

Use of the hybrid junction type of IF input circuit shown in figure 12-36 (B) insures suppression of local oscillator noise despite imbalance in the IF impedances of the crystals. When all entries of the IF hybrid junction are terminated in a load that is the conjugate of

CHAPTER 3

MYOLOGY AND SPECIALIZED TISSUESS

MUSCLES

The study of muscles is important because it involves all body movement. Whatever man does in the way of walking, talking, breathing, eating, and even in the circulation of blood is the result of some muscle action.

If you were to remove the skin from the body, you would not see bone. You would see muscles covering the bone. In addition to providing the means of movement, these muscles along with the skeletal bones, provide support and shape.

Muscle comprises from 40% to 50% of total body weight. There are approximately 500 muscles large enough to be seen with the naked eye. There are, however, many thousands of a microscope. The diameter of a single muscle fiber is approximately one-tenth of a micron, much smaller than a strand of hair.

This chapter will discuss the structure, action and location of the more prominent muscles of the body.

Terminology

1. MUSCLE—Tissue or organs which by contraction produce motion.
2. TENDON—A thin strong white cord-like substance connecting muscle to bones.
3. LIGAMENT—A strong non-fibrous band of tissue which holds bone together or organs in place.
4. FASCIA—Fibrous tissue surrounding muscle fibers, keeping them in place during movement.
5. ORIGIN—The more fixed attachment of a muscle: The Fulcrum.
6. INSERTION—The more moveable attachment of a MUSCLE.
7. IRRITABILITY (Excitability)—The property of receiving and responding to stimuli.
8. CONTRACTIBILITY—Property which enables a muscle to become shorter or thicker.
9. ELASTICITY—Property by which muscle returns to its original shape. Ability to stretch.
10. MUSCULAR TONE (Tonicity)—Property which gives muscle a certain firmness and maintains a steady pull upon their attachments.
11. MOTOR NERVE—A nerve which stimulates muscle to contract.
12. RIGOR MORTIS—The stiffening of muscles after death.

Classification

Muscles are classified according to structure. Those of the skeleton are striated (striped), and are called voluntary. These muscles are concerned with voluntary action or thought (arms, legs, face, etc.) The muscles of the viscera are called involuntary, non-striated or smooth. These are the automatic muscles which act without conscious thought. The exception to the rule is the heart muscle—it is a faintly striated, involuntary muscle.

Structure

All muscles are made up of long slender tissue cells called fibers. These muscle fibers are bound together to form the muscle. At one end of some muscles are long white tendons, something like guy wires, which extend to the fingers and feet. This not only makes for graceful movements of the fingers but also reduces the amount of bulk that would be necessary if muscles had extended around the fingers.

Muscles seldom act alone, but usually in muscle groups, and these muscle groups are held together by white fibrous tissue called fascia.

10234

10235

Action

Muscular action has two distinct mechanisms. One is mechanical, the other chemical. The mechanical action of the muscle is innervated by a motor nerve and consists of a shortening or thickening of the muscle fibers. Muscular action seldom occurs singly. In general, there is action by two muscles, one opposing the other.

The chemical action that takes place is still not clearly understood. In general, this action can be divided into two stages, contraction and recovery. In the contraction stage, two protein substances react to create energy. In the recovery stage, oxygen and glycogen are used to provide energy and react with lactic acid releasing carbon dioxide and water.

When a muscle contracts, it produces chemical waste products (carbon dioxide, lactic acid, and acid phosphate), which make the muscle more irritable. If contraction is continued, the muscle will finally cramp up and refuse to move. This condition is known as fatigue. If it is carried too far, the muscle cells will not recover and permanent damage will result. Muscles, therefore, need rest to allow the blood to carry away the waste materials and bring in fresh glucose, oxygen and protein to restore the muscle protoplasm and the energy that was used.

The importance of exercise for normal muscle activity is clear, but excessive muscle strain is damaging. For example, if a gasoline motor stands idle, it eventually becomes rusty and useless. Similarly, a muscle cell that does not work becomes weak and flabby. On the other hand, a motor that is never allowed to stop and is forced to run too fast or do too much heavy work soon wears out so that it cannot be repaired. In the same way, a muscle cell that is forced to work too hard without proper rest will be damaged beyond repair. Violent exercise is never good. Exercise should be adapted to the individual and should never be carried to the point of extreme fatigue.

During exercise, massage, or performance of ordinary activities, the blood supply of muscles is increased. This brings in fresh food materials, carries away waste products more quickly, and enables the muscles to build up and restore their efficiency and tone.

When a muscle dies, it becomes solid and rigid and no longer reacts. This stiffening which occurs from ten minutes to seven hours after death is called rigor mortis.

Muscular Function

Muscles do three things for us:

1. Provide movement, as in peristalsis in the intestines.
2. Maintain our posture through muscle tone, as in the muscles of the head, neck and shoulders, which keep the head erect.
3. Produce heat. Chemical changes that take place during muscle activity, such as mild exercise on cold days, keep us warm.

Important Functional Muscles

MASSETER.—This muscle raises the mandible or lower jaw to close the mouth. It is the chewing muscle in the mastication of food. It originates in the zygomatic process and adjacent parts of the maxilla, and is inserted in the mandible.

TEMPORAL.—This muscle assists the masseter and draws the mandible backward. It has its origin in the temporal fossa and is inserted in the cornoid process of the mandible.

STERNOCLEIDOMASTOID.—This muscle is located on both sides of the neck, acting as a lever. It acts by pulling the head left or right on the shoulder. Bilaterally, it acts by flexing the head towards the chest or shoulders. It originates in the sternum and clavicle with its insertion in the mastoid process of the temporal bone.

TRAPEZIUS.—A broad diamond shaped pair of muscles on the upper back which raise or lower the shoulders. They cover approximately a third of the back. They originate in a large area, the 12 thoracic vertebrae, 7th cervical and the occipital bone, and have their insertion in the clavicle and scapula.

DELTOID.—Abducts the arm and has its origin in the clavicle and spine of the scapula. Its insertion is on the lateral side of the humerus. It fits as a cap over the shoulder, and is frequent site of intra-muscular injections (1cc or less).

10236

PECTORALIS MAJOR.—Rotates the arm inwards; abducts and draws the arm across the chest. It originates in the clavicle, sternum and cartilages of the true ribs and the external oblique muscle. Its insertion is found in the greater tubercle of the humerus. It is the prominent chest muscle.

LATISSMUS DORSI.—A broad flat muscle which rotates the arm inward. It covers approximately a third of the back on each side. It arises from the upper thoracic vertebrae to the sacrum and the posterior portion of the crest of the ilium. These fibers converge to form a flat tendon which has its insertion in the humerus.

BICEPS BRACHII.—It flexes the elbow and supinates the hand. In the anatomical position, it is located on the anterior surface of the upper arm. It has its origin in the outer edge of the glenoid cavity and its insertion in the tuberosity of the radius. The brachialis and the triceps are opposing muscles. The triceps is the great extensor of the forearm, while the brachialis is the flexor of the forearm.

DIAPHRAGM.—This muscle, besides being the primary muscle of respiration, forms the floor of the thoracic cavity and the ceiling of the abdominal cavity. It modifies the size of the thorax (chest) and abdomen vertically. It has two large openings—the esophageal and the vena caval. A third opening lies behind the diaphragm, the aortic opening. These openings allow for the passage of nerve and blood vessels.

GLUTEUS MAXIMUS.—It is the large muscle of the buttock. This muscle extends the femur and rotates it outward. It has its origin in several areas; the crest of the ilium, posterior surface of the lower sacrum, and the side of the coccyx. The gluteus maximus is the site of choice for massive intra-muscular injections.

SARTORIUS.—It is the longest muscle of the body, extending obliquely across the thigh anteriorly. It flexes the thigh on the hip and the leg upon the thigh. It also rotates the thigh outward. It is often known as the "tailors muscle."

GRACILIS.—A long slender muscle located on the inner aspect of the thigh. It assists in adducting the thigh and flexing the leg. It originates in the symphysis pubis and has its insertion in the medial surface of the tibia, below the condyle.

BICEPS FEMORIS.—It acts to flex the leg on the thigh and to extend the thigh. It originates from the tuberosity of the ischium and short head of the femur. It has its insertion in the lateral side of the head of the fibula and lateral condyle of the femur. The biceps femoris is often called a hamstring muscle. (The semitendinosus and semimembranosus are also called hamstring muscles. They lie beneath and laterally to the biceps femoris.)

CALF MUSCLES.—The main muscles of the calf are the gastrocnemius and the soleus. The gastrocnemius originates in the heads of the femur and the soleus from the head of the fibula and medial border of the tibia. Both are inserted in a common tendon called the calcaneus or achilles tendon. This tendon has its insertion in the heel or calcaneus bone. These muscles extend the foot at the ankle.

SPECIAL TISSUE

BURSAE

A bursa is a small sac of specialized tissue containing viscid fluid. Bursae are located at various places in the body where friction would ordinarily occur as between skin and bone, tendon or ligament and bone, or between muscles. Bursae may become inflamed (bursitis), and movement then elicits pain. Principal bursae are:

SUBDELTOID BURSA in the shoulder, located between the deltoid muscle and the head of the humerus.

PREPATELLAR BURSA anterior to the kneecap. Inflamation here with formation of fluid, is known as "housemaid's knee" because it occurs frequently in individuals who kneel while scrubbing floors or performing other housekeeping chores.

OLECRANON BURSA between the olecranon process and the skin over the elbow. When inflammed this is known as "tennis elbow", or "student's elbow", the latter because students frequently lean on their elbows for long periods and irritate the fluidfilled sac.

10237

Figure 3-1.—Important superficial muscles, Anterior view.

10238

Figure 3-2.—Important superficial muscles, Posterior view.

10239

SPECIAL MEMBRANES

Lining tissues of the body are termed membranes and are serous, synovial, mucous, or cutaneous.

SEROUS MEMBRANES are so named because they are moistened by a fluid resembling the serum of blood. Serous membranes proper are found in the form of moistened covering of lungs, heart, brain, spinal cord, and organs contained in the abdominal cavity.

SYNOVIAL MEMBRANES are those lining joints; the bursae have a similar lining. These membranes secrete a very small amount of fluid.

MUCOUS MEMBRANES are those lining the canals and cavities of the body which communicate with the air such as the alimentary canal and its branches, the respiratory tract and its connections, and the genitourinary tract.

CUTANEOUS MEMBRANE is the outer covering of the body, the skin. This is the largest organ of the body and important for its protective functions such as sensation and temperature control.

CHAPTER 4

INTRODUCTION TO THE CIRCULATORY SYSTEM

The blood vascular system is the primary fuel supplier of the body. It is composed of a pump, the heart; feed lines, the arteries; usage points, the capillaries; and waste lines, the veins. The transportation media is the blood. This system in our body is a closed circuit. At no place does it have access to the other tissues of the body except at the capillaries. (See fig. 4-5.)

OSMOSIS, (a transfer of fluids through the cell walls,) is the method of feeding body tissues and eliminating waste materials. This occurs in the smallest of the blood vessels called capillaries.

BLOOD

Blood is very complex liquid. It is a combination of separate particles suspended in a liquid. It is about five times as viscous as water and comprises 1/12 of the body weight. In the average adult, there are approximately 6 quarts of blood. Its color ranges from a bright to dull red, depending on the oxygen content.

The blood functions as the transportation media of the body. It serves many purposes, the most important of which are:

1. Oxygenation
2. Maintains body temperature
3. Aids as a defense against invasion of harmful bacteria
4. Provides transport of nutritive and waste products
5. Maintains normal acid base balance of tissues
6. Provides a defense against bleeding called clotting
7. Acts as a small trucking concern to transport products made in one tissue to another (Hormones and other internal secretions.)

Blood is composed of plasma, red cells, white cells, and platelets.

PLASMA is the fluid portion of the blood in which is suspended discrete particles, the cells and platelets. It is a clear, slightly alkaline, straw colored liquid. It is the total liquid of the blood including Fibrinogen, that portion which contributes to coagulation. Plasma consists of water with proteins, carbohydrates, fats, vitamins, chemicals, hormones, antibodies, and enzymes in solution.

BLOOD SERUM is a clear, pale yellow liquid. It is the liquid portion of the blood remaining after coagulation.

RED BLOOD CELLS, or erythrocytes are circular red saucer like discs with pale center. They contain no nuclei and are formed primarily in the red bone marrow. Blood of the average man contains approximately 30 trillion ($3x10^{12}$) red blood cells or about 5 million per cubic millimeter. Women have slightly less, about 4.5 million per cubic millimeter. Under emotional stress, strenuous exercise, maintained high altitudes, and certain disease conditions, the quantity of red cells is variably increased.

During the development of the red blood cells, a substance called hemoglobin is combined with it. This substance is a combination of heme (an iron containing pigment) and globin (a protein). HEMOGLOBIN is the key of the red cells ability to carry oxygen and carbon dioxide. The red cells deliver oxygen to the body tissues and usually only a fifth to a fourth of the oxygen is released. This is due to the tissues' inability to absorb more. The remainder of the oxygen is held in reserve by the red cells for an emergency. Carbon dioxide is picked up by the same cells and discharged via the lungs.

The color of the red blood cell is determined by the hemoglobin content. Bright red or arterial blood is due to the combination of oxygen and hemoglobin. Dark red or venous blood is the result of hemoglobin combining with carbon dioxide.

The life span of a red blood cell is about 100 to 120 days. The spleen is the "graveyard" where old, worn out cells are removed from the blood stream.

10241 10240

The red blood cell is dependent upon a normal concentration of salts in the blood. Any variation from this normal will cause the cell to become more fragile.

The amount of various salts and substances dissolved in the blood plasma is about nine-tenths of 1 percent (0.9 percent). A solution of this strength is called ISOTONIC or PHYSIOLOGIC. It has the same osmotic pressure (a pressure which brings about equalization of solutions of different concentrations) as blood plasma and tissue fluid.

Solutions of a lower concentration of blood plasma (hypotonic) when rapidly introduced into the blood stream cause the red blood cells to absorb the water from the plasma (hydrolyzed). This causes them to swell and eventually burst, liberating the hemoglobin. The introduction of a higher concentration (hypertonic) will cause them to shrink and become notched (crenated).

Glucose solutions are frequently given in higher concentrations, 5 and 10 percent or more. But because they are given at a slow rate, the blood plasma does not undergo rapid change and can compensate rapidly. This is accomplished by the transfer of water from the tissues into the blood stream and the red cells suffer no change.

WHITE CELLS vary in size and are called leukocytes. There is about 1 white cell to every 600 red cells. The normal adult has a white count from 6 to 8 thousand per cubic millimeter. This will often rise to 10,000 with exercise, strenuous activity, cold baths, and even digestion. (This is thought to be caused by the increased circulation of the body).

White cells can be divided into three distinct types; granulocytes, lymphocytes, and monocytes. The lymphocytes are manufactured in the lymph tissue, while the granulocytes are thought to be manufactured in the red bone marrow. The monocytes are found in the reticular tissue of the liver, spleen and lungs.

White cells have a movement that is called AMEBOID which permits them to leave the blood stream through the capillary wall and attack pathogenic bacteria. They can travel anywhere in the body and are often named "the wandering cells".

White cells function as regulators. They protect the body from disease-bearing bacteria. They accomplish this by engulfing the foreign body, a condition called phagocytosis. When they are undermanned, more are produced causing an increase in the number of white cells, and a condition known as leukocytosis exists. Another way they protect the body from disease is by the production of bacteriolysins which dissolve the foreign bacteria. The second most important function is that of aiding in blood clotting.

BLOOD COAGULATION.—To protect the body from excessive blood loss, blood has its own power to coagulate or clot. Under conditions wherein blood constituents and linings of vessels are normal, circulating blood will not clot. Once it escapes from its vessel, however, a chemical reaction begins which causes it to solidify. The clot formed is at first fluid but soon becomes thick and then "sets" into a soft jelly (much the same way jello sets), which soon becomes firm enough to act as a plug. This plug is the result of a swift, sure reaction which changes one of the soluble proteins, (Fibrinogen), into a insoluble protein, (fibrin), whenever injury occurs.

In addition to Fibrinogen, other necessary elements for clotting are calcium salts, a substance called prothrombin, blood platelets, and various factors which are necessary for the completion of the successive steps in the coagulation process. Once the fibrin plug is formed, it quickly enmeshes the red and white cells and draws them tightly together. As the mass shrinks and the clot forms, a yellowish clear liquid called blood serum is squeezed out. This clot also serves as the network for the growth of new tissues in the process of healing.

Normal clotting time is 3-5 minutes. If any of the necessary clotting substances are missing, severe bleeding will ensure.

Hemophilia is an inherited disease characterized by delayed clotting of the blood and consequent difficulty in controlling hemorrage. It occurs mainly in the male species.

CIRCULATORY SYSTEM

The circulatory system is comprised of the heart and blood vessels. The heart, a muscular pump, propels the blood through the blood vessel system of closed tubes, composed of arteries, capillaries, and veins.

Heart

The heart is a hollow organ somewhat larger than the closed fist, located anteriorly in the chest to the left of center, and is the major

10242

structure of the mediastinum. Somewhat cone-shaped, the apex of the heart is directed downward and to the left. Lying obliquely in the chest, much of the base of the heart is immediately posterior to the sternum.

The heart is enclosed in a membranous sac, the pericardium. The smooth surface of the heart and pericardium are lubricated by a serous secretion, pericardial fluid. The inner surface of the heart is lined with a delicate serous membrane, ENDOCARDIUM, similar to and continuous with that of the inner lining of blood vessels.

The interior of the heart is divided into two parts by a septum. In each half there is an upper chamber, the atrium, which receives blood from the veins; and a lower chamber, the ventricle, which receives blood from the atrium and pumps it out into the arteries. The opening between the chambers on each side are supplied with one-way or check valves which prevent the backward flow of the blood stream. The right valve is called the tricuspid and the left valve is the mitral. The outlets of the ventricles are supplied with similar valves. On the right, the pulmonary valve is at the origin of the pulmonary artery and on the left, the aortic valve at the origin of the aorta. (See fig. 4-1.)

Figure 4-1.—Diagram of the heart.

Physiologically, the heart acts as two separate pumps. The right side receives the deoxygenated blood in the right atrium from the various regions of the body. It passes through the tricuspid valve into the right ventricle where it is pumped through the pulmonary artery via the pulmonary valve to the lungs. There it receives a fresh supply of oxygen and releases carbon dioxide. As it passes into the left atrium from the pulmonary veins, the pulmonary circulation is completed. The left side receives oxygenated blood from the lungs into the left atrium via the pulmonary veins and passes via the mitral valve into the left ventricle, which pumps it into all the body areas through the arteries. This is called systemic circulation.

The heart acts by contraction and relaxation. When the heart contracts it is with a wringing motion forcing the blood into the arteries. Each contraction of the heart is followed by limited relaxation or dilation. Cardiac muscle never completely relaxes but always maintains a degree of tone. Contraction of the heart is systole and is the period of work. Relaxation of the heart with limited dilation is diastole, and is the period of rest. A complete cardiac cycle is the time from the onset of one contraction or heart beat to the onset of the next.

During the cycle, the blood coursing through the valves and chambers of the heart produce sounds, conveyed to the ears of the physician by means of a stethoscope. Variations in the rhythm, intensity, or character of these sounds furnish valuable clues for the determination of heart disease.

The heart has its own blood vessel system. The right and left coronary arteries which arise from the aorta immediately as it leaves the heart; and the coronary sinus, which collects the venous blood from the heart and empties it directly into the right atrium.

The normal heart rate is about 72 beats per minute. This varies with age, weight, sex, amount of exercise and body temperature. It beats about 100,800 times a day. Blood Pressure is the force exerted by the blood within the closed hydraulic system of arteries. It is the result of five factors:

1. The pumping of the heart.
2. The peripheral resistance to the circulating blood.
3. The quantity of blood in the system.
4. The viscosity of the blood.
5. The elasticity of the arterial walls.

10243

the impedance faced by the load, the two crystals (constituting one pair of entries) are decoupled and the two resonant circuits (constituing the other pair) are also decoupled. If the resonant load entries remain matched, the amount of IF signal power coupled from one crystal to the output terminals is independent even if the IF impedance of the other crystal does not match the arms. Furthermore, the IF components of noise cancel in the output circuit independently of the IF crystal impedance as long as the crystals develop equal IF noise voltage. The IF components of noise appear only across the L′, C′, and R′ arm. If crystals are tested for equal conversion gains while loaded by the conjugate of the IF impedance of a typical crystal, equal IF noise voltages can be expected when the crystals are employed in the circuit.

Terminating the IF output entry in a matched load does not in general insure minimum noise figure. Mismatching the output entry in order to minimize the noise figure alters the load the push-pull IF echo signals and thus reduces the echo signal power delivered to the load but does not alter the load for the IF components of noise which are applied to T3 in parallel. The local oscillator noise suppression property of the mixer is therefore retained.

1022K

The highest pressure is called systolic blood pressure because it is caused when the heart is in systole, or contraction. A certain amount of blood pressure is maintained in the arteries even when the heart is relaxed. This is the diastolic blood pressure, because it is present during diastole, or relaxation of the heart. The difference between systolic and diastolic pressure is known as pulse pressure.

Normal blood pressure for young adults; systolic 120-150 mm of mercury; diastolic 70 to 90 mm of mercury. This varies according to weight, age, and general condition of the individual. Females have a lower blood pressure than males.

Blood Vessels

Blood vessels of the body fall into three distinct classifications.

1. Distributors—Arteries and arterioles
2. Exchangers—Capillaries
3. Collectors—veins and venules

ARTERIAL CIRCULATION (BODY'S BLOOD SUPPLY.—The system of arteries and arterioles is similar to that of a tree, with the aorta as the trunk, the arteries as large branches and the arterioles as small twigs.

ARTERIES are elastic tubes, constructed to withstand high pressures. The smallest branches of the arteries are called arterioles.

The aorta is the largest tube-like structure which arises from the left ventricle of the heart and arches upward over the left lung and then down along the spinal column through the diaphragm. Along the way, arteries branch off to the head, neck, arms, chest and abdomen before finally dividing to send arteries down both legs. (See fig. 4-2.)

The only branches of the ascending aorta are the coronary arteries which supply the heart with blood.

There are certain branches of the aorta with which you should be familiar, since these often must be compressed to control hemorrhage. In the first chapter on first aid you will learn the pressure points which must be compressed if severe arterial hemorrhage is to be controlled.

Three large arteries arise from the aorta as it arches over the left lung. First, the innominate artery which divides into the right subclavian artery, to supply the right arm and the right common carotid to supply the right side of the head. The second branch is the left common carotid which supplies the left side of the head. The third branch from the arch of the aorta is the left subclavian, which supplies the left arm.

The carotids divide into internal and external branches, the external supplying the muscle and skin of the face; the internal supplying the brains and the eyes.

The subclavian arteries are so named because they run underneath the clavicle. They supply the upper extremity branching off to the back, chest, neck, and brain via the spinal column. (See fig. 4-2.)

The large artery going to the arm is called the axillary. This divides into the ulnar and radial arteries. The radial artery is the one at the wrist which you feel to take the pulse of your patient. It is located on the thumb side. (See fig. 4-3.)

The abdominal aorta gives off branches to the abdominal viscera, including the stomach, liver, spleen, kidneys and intestines. It finally divides into the left and right common iliacs which send large arteries to the lower extremities. On entering the thigh, the artery is called the femoral artery, and here again, on the inner aspect of the thigh, is a pressure point (the groin) that you should learn. This artery is frequently injured in fracture accidents and must be compressed to control hemorrhage. (See fig. 4-4.)

At the knee, the femoral becomes the popliteal. It is located posteriorly and can be compressed against the tibia or lower end of the femur.

CAPILLARIES.—At the end of the arterioles is a system of minute vessels which vary in structure, but which are spoken of collectively as capillaries. It is from these capillaries that the tissues of the body are fed. (There are approximately 60,000 miles of capillaries in the body). As the blood passes through the capillaries it releases oxygen and nutritive substances to the tissues and takes up various waste products to be carried away by the veins.

VEINS comprise a system of vessels which collect blood from the capillaries and carry it back to the heart. Veins begin as tiny venules which are formed from the capillaries. Joining together as tiny rivulets, they connect and form a small stream. The force of muscles contracting adjacent to veins aids in the forward propulsion of blood on its return to the heart. Valves, spaced frequently along the larger veins, prevent the backflow of blood.

10244

Figure 4-2.—Arteries and veins of torso.

10245

Figure 4-3.—Arteries and veins of the upper extremity.

BLOOD COLLECTION SYSTEMS (Venous circulation).—Since arterial blood arises at the heart, we trace arteries from the heart. To return blood to the heart, we trace veins from their smaller extremities called venules back through larger veins. There are three principal venous systems in the body:

1. Pulmonary . . those from the lungs
2. Portal . . returns blood from the intestines, spleen and liver
3. Systemic . . those from the rest of the body.

The PULMONARY SYSTEM is comprised of four vessels, two from each lung, which empty into the left atrium. These are the only veins in the body that carry freshly oxygenated blood.

The PORTAL SYSTEM is comprised of those veins which drain venous blood from the abdominal part of the digestive tract (except the lower rectum), spleen, pancreas, and gallbladder, and deliver it to the liver. There it is distributed within the liver by a set of venous capillaries. The blood in the portal system conveys absorbed substances from the intestinal tract to the liver for storage, alteration, or detoxification. From the liver the blood flows through the hepatic vein to the inferior vena cava.

The SYSTEMIC SYSTEM is divided into deep and superficial groups. The superficial veins lie immediately under the skin and drain the skin and superficial structures. The deep veins, usually located in the muscle or deeper layers, drain the large muscle masses and various other organs. They usually lie in close relation to the large arteries which supply the various organs of the body, (see fig. 4-2) and usually have the same name as the artery they accompany.

The superficial veins of the head unite to form the external juglar veins. They drain blood from the scalp, face, and neck, and finally empty into the subclavian veins.

The veins which drain the brain and internal facial structures are the internal jugular veins. These combine with the subclavian veins to form the innominate veins which empty into the superior vena cava. (Fig. 4-2.)

Figure 4-4.— Arteries and veins of the lower extremity.

10246

The veins of the upper extremity begin at the hand and extend upward. There is one vein, extremely valuable, the median cubital, which crosses the anterior surface of the elbow. It is the vein most commonly used for intravenous injections and infusions.

The deep veins of the upper arm unite to form the axillary vein in the upper arm, which unites with the superficial veins to form the subclavian vein. This later unites with other veins to form the innominate and eventually, after union with still more veins, forms the superior vena cava.

In the lower extremity (fig. 4-4), a similar system drains the superficial areas. One in particular, the great saphenous vein, originates on the inner aspect of the foot and extends up the inside of the leg and thigh to join the femoral vein in the upper thigh. This vein is sometimes used for intravenous injections at the ankle. The superficial venous system of the leg often becomes varicose or excessively dilated, particularly in those persons whose occupations require long periods of standing, such as barbers, surgeons, and policemen. When this develops, the venous valves become incompetent, allowing stagnation of blood in the dependent extremity. Under these circumstances, varicose ulcers frequently develop. Ligation at several points along the system will force the venous return into the deep venous system and restore normal venous circulation.

The veins from the lower extremities unite to form the femoral vein in the thigh which becomes the external iliac vein in the groin. Higher in this region, it unites with the hypogastric vein from the lower pelvic region to form the common iliac vein. The two common iliac veins unite to form the inferior vena cava.

The veins from the abdominal organs, with the exception of the portal system, empty directly or indirectly into the inferior vena cava, while those of the thoracic region eventually empty into the superior vena cava.

LYMPHATIC SYSTEM

LYMPH is the fluid which provides transportation in the lymphatic system. It is similar to blood plasma and is generally considered to be the same as interstitial fluid. (The fluid which bathes all body tissues.)

There is a continual interchange of fluids between the blood and tissues with most of the tissue fluid returning to the circulation by way of the venous capillaries which feed into the larger veins. Large protein molecules which escape from the arterial capillaries cannot reenter the circulation through the smaller intracellular spaces of the venous capillaries. These particles along with dead cells, bacterial debris, injected substances, and larger particles are absorbed by the lymphatic capillaries.

Lymph is usually clear, but following the ingestion of a fatty meal the lymph contained in the lymphatic vessels that drain the small intestines appears milky. This milky lymph called CHYLE is caused by the absorption of the fat globules.

LYMPH VESSELS and lymph nodes form a network throughout the body. Similar to the venous system, lymphatic capillaries collect lymph from the tissue spaces and, by means of a system in which small vessels unite to form larger ones, carry the lymph toward the heart. Along the paths of the larger lymphatic vessels are valves which prevent the backflow of fluid.

Lymphatic channels from the upper half of the right side of the body converge to form the right lymphatic duct which empties into the right subclavian vein. Drainage from the rest of the body is by way of the thoracic duct, the largest lymphatic vessel, which empties into the left subclavian vein.

LYMPH NODES are small bean-shaped bodies of lymphatic tissue found in groups of 2 to 15 along the course of the lymph vessels. Just beneath the skin, they usually occur singly. Nodes vary in size and act as filters to remove bacteria and particles from the lymph stream. Lymph nodes also participate in the manufacture of white blood cells called lymphocytes, and thereby participate in the immunity functions of the body.

010247

Figure 4-5.—Schema of circulation.

10248

CHAPTER 5

THE RESPIRATORY SYSTEM

Respiration (breathing) is one of the vital functions of the body. It is the source of oxygen for the body tissues and the main exhaust for carbon dioxide.

There are two distinct phases of respiration;

1. Physical or mechanical respiration involves the motion of the diaphragm and rib cage, causes air to be inhaled or exhaled. This skeleto-muscular action resembles that of a bellows.

2. Physiological action involves an exchange of gases, oxygen and carbon dioxide, at two points in the body. The first is the transfer which occurs in the lungs between the incoming oxygen and the carbon dioxide in the capillaries of the lungs (external respiration). The second transfer occurs when the oxygen replaces the carbon dioxide in the cellular tissue (internal respiration). The degree of transfer depends upon the amount of oxygen carried by the capillaries to the tissues. Normally, the oxygen in the capillaries will exchange with an equal volume of carbon dioxide.

ANATOMY OF THE RESPIRATORY SYSTEM

Physically, the air enters the nostrils and passes through the pharynx, larynx, trachea, and bronchi into the bronchioles which form a network around the air sacs called alveoli where the exchange of oxygen and carbon dioxide is made.

NASAL CAVITY.—The air enters the nasal cavity thru the nostrils or nares. Lining the nasal passages are hairs (cilia), which together with the mucous membrane entrap and filter out dust and other minute particles. In the chambers of the nasal cavity, the air is warmed and moistened.

The PHARYNX, or throat, is a tubular passageway which lies behind the nasal passages and the mouth, between the base of the skull and the larynx and the beginning of the esophagus. It is divided into three parts: the nasopharynx, the oropharynx, and the laryngopharynx. The upper portion (nasopharynx) is an air passage only. The lower portion serves both the respiratory and digestive tracts as a common passageway; it is the corridor between the mouth and the esophagus, and the nasal passages, larynx and trachea.

The LARYNX, or voice box, is a triangular, cartilaginous structure located between the root of the tongue and the trachea. During the act of swallowing, it is pulled upward and forward placing it under the shelter of the base of the tongue and the epiglottis (a lidlike structure of cartilage which covers the entrance to the larynx) which acts as a protecting shelf to deflect food from the entrance of the air passageway (trachea).

All air going to or from the lungs must pass through the larynx. During this air passage, vibrations of the vocal cords may be produced, resulting in the sounds of speaking and singing.

The TRACHEA, or windpipe, begins at the lower end of the larynx and terminates by dividing into the right and left bronchi. It is a long cylindrical tube composed of 16 to 20 "C" shaped cartilinagous rings embedded in a fibrous membrane. These give firmness to the walls, preventing their collapse.

The trachea is lined with microscopic waving hairs (cilia) and mucous glands. The cilia entraps dust and foreign material and also propels secretions and exudates from the lungs to the mouth where they can be expectorated.

The BRONCHI are the terminal branches of the trachea which carry the air through their bronchioles to the alveoli. (See fig. 5-2.)

10249

chest to return to normal and original size thus expelling the air from the lungs.

The lungs, when filled to their full capacity, hold about 4,500 cc. of air but only 500 cc. of air is breathed out at a normal quiet expiration. This air that is changed with each respiration is called tidal air. The amount of air that is breathed out or in may be increased by forceful expiration and inspiration. The amount of air left in the lungs after forceful expiration is about 1,000 cc., and is known as residual air. Under normal conditions the reserve supply of air left in the lungs is about 2,600 cc.

Certain sounds are produced by passage of air into and out of the lungs. These sounds vary in diseases of the lungs. Doctors depend upon these sounds of the lungs during respiration to diagnose pneumonia, bronchiectasis, and other diseases of the lungs.

ABNORMALITIES OF BREATHING

The following terms are used to describe breathing and *significant variations in exchanges* of respiratory gases:

Eupnea — Ordinary quiet respiration.

Brandypnea — Abnormal slowness of breathing.

Tachypnea — Excessive rapidity of respiration.

Hypopnea — Abnormal shallowness and rapidity of respiratory movements.

Dyspnea — Labored or difficult breathing.

Hyperpnea — Applies to the initial state of dyspnea when the rate and depth of respiration is simply being increased.

Apnea — A condition in which there is a temporary cessation of breathing.

Cheyne-Stokes — The respirations increase with force and frequency up to a certain point, and then decrease until they cease altogether. There is a short period of apnea; then the respirations begin again, and the cycle is repeated.

Stertorous — Breathing with abnormal snoring sounds.

Rales — Abnormal respiratory sounds, either moist or dry depending upon the fluid in the air passages, which are classified according to their location as bronchial rales, laryngeal rales.

Rhonchus — A rattling sound in the throat due to partial obstructions; also a dry course rale in the bronchial tubes.

CHAPTER 6

ELEMENTARY FUNCTION AND DESCRIPTION OF THE DIGESTIVE SYSTEM

The digestive system consists of the alimentary tract — mouth, esophagus, stomach and intestines - plus the accessory organs of digestion. As food passes along the alimentary tract digestion and absorption occur and eventually waste material is eliminated. Secretions of the accessory organs assist in preparing food for absorption and use by the tissues of the body.

Digestion is both mechanical and chemical. Mechanical digestion occurs when food is mechanically chewed, swallowed and churned by peristalsis. Waste is evacuated when the bowels move. Chemical digestion consists of changing the various foods, with the aid of enzymes, into solutions and simple compounds. Carbohydrates (starches and sugars) change into simple sugars (glucose); fats change into fatty acids; and proteins change into amino acids.

The ALIMENTARY CANAL is about 30 feet long and is divided into eight parts or sections:

- Mouth cavity
  - Teeth
  - Tongue
- Pharynx
- Esophagus
- Stomach
- Small intestines
  - Duodenum
  - Jejunum
  - Ileum
- Large intestines
  - Cecum
  - Ascending Colon
  - Transverse Colon
  - Descending Colon
  - Sigmoid Colon
- Rectum
- Anus

ACCESSORY ORGANS that aid the digestive process are:

- Salivary glands
- Pancreas
- Liver
- Gall bladder
- Intestinal glands

Mouth Cavity

The TEETH break up the food into small particles before it is swallowed. Here the salivary glands secrete saliva to aid in the digestion of the sugar and starches. Approximately 1500 milliliters or 1 1/2 quarts are secreted daily. This secretion moistens the food, makes it easier to chew, and lubricates the food mass to aid in swallowing. Saliva contains one principle enzyme, ptyalin which begins the digestion of starches by changing them into a complex sugar, maltose.

The TONGUE is a muscular organ attached to the lower jaw at the back of the mouth and is the chief organ of taste. It assists in mastication, swallowing, and speech.

The Pharynx

The pharynx is the passageway between the mouth and the esophagus and is shared with the respiratory system.

The Esophagus

The Esophagus is a muscular tube about 25 centimeters (10 inches) long. It is the passageway between the pharynx and the stomach. By means of waves of muscular contractions (peristalsis), food is pushed along this tube to the stomach. When peristalsis is reversed vomiting occurs. Vomiting occurs with overeating, intestinal disease and certain toxic drug reactions.

The stomach and intestines are enclosed in the space between the diaphragm and the pelvis, called the abdominal cavity. This cavity is lined with serous membrane, the peritoneum. The peritoneum covers the intestines and the organs, and by secreting a serous fluid prevents friction between the adjacent organs. Layers of peritoneum that extend from the body wall to an organ and suspend it are called mesentery. The mesentery carries blood vessels to the organs.

66S010252

Figure 6-1.—The digestive system.

The Stomach

The stomach is an enlargement of the gastro-intestinal tract and is somewhat bean-shaped. It is connected to the esophagues via the cardiac sphincter and to the small intestine via the pyloric sphincter. These sphincters are muscular rings or valves to prevent the escape of food during the stomach's stage of digestion.

The stomach is the warehouse for swallowed materials. It assists in the chemical change of food materials. Small glands in the walls of the stomach secrete gastric juices. Pepsin and hydrochloric acid are the principal components of the gastric juice. Hydrochloric acid inhibits the action of ptyalin, tends to kill bacteria as it enters the stomach and releases pepsin from pepsinogen. It also helps to regulate the action of the pyloric sphincter. Pepsin acts solely on proteins changing them into simpler substances. As the food is refined in the stomach it becomes semi-liquid (chyme). Normally after the first hour the stomach is half empty, and after the sixth hour the entire meal has emptied through the pyloric sphincter into the small intestine.

Small Intestines

The small intestine is a muscular convoluted tube about twenty three feet long, attached to the posterior abdominal wall by its mesentery. The mesentery is gathered together like a fan to allow the intestines to coil in a small space. The small intestines receives digestive juices from three accessory organs: pancreas, liver and gall bladder. It is divided into three continuous parts: duodenum, jejunum, and ileum.

The DUODENUM is a tube about ten inches long which forms a C-shaped curve around the head of the pancreas, posterior to the liver. It is lined with mucous membrane which contains small glands. These glands secrete intestinal juices containing the enzymes: carbohydrases, peptidases and lipase.

The JEJUNUM is the middle part of the small intestines, about seven and one-half feet long, and its enzymes continue the digestive process.

The ILEUM is the last and longest part of the small intestines. Most of the absorption of food occurs in the ileum where fingerlike projections (villi) provide a large absorption surface. After injestion it takes twenty minutes to two hours for the first portion of the food to pass through the small intestines to the beginning of the large intestines.

Large Intestines

The unabsorbed food or waste material passes through the cecum into the large intestines. Twelve hours after the meal, most of the waste material will be in the colon. The waste material passes through the colon where the water content is absorbed by the body. Twenty four hours after the meal the waste material reaches the rectum.

The Rectum

When waste material reaches this point the body has a desire to defecate. If this desire is ignored constipation may result because of additional water absorption. The rectum is a tube about five inches long that follows the contour of the sacrum and coccyx until it curves back into the short anal canal.

S2S0410253

CHAPTER 13

UHF COMMUNICATIONS

Some of the advantages and general characteristics of UHF and microwave equipment and techniques have been discussed in the preceding chapter. In that discussion, the advantages of high frequency (short wavelength) for radar use were pointed out. In addition, mention was made of the factors of size and weight.

An overall statement as to an advantage of high-frequencies is that the trend toward miniaturization becomes a reality. This is highly desirable for aviation equipment. Circuit components generally become smaller as the frequency increases. Furthermore, it is possible to construct directive antennas of smaller size than when lower frequencies are used. Small directive antennas and compact circuit components are important considerations in airborne equipment where space and weight are major problems.

From the standpoint of communications specifically, another advantage of UHF should be mentioned, aside from the fact that circuit components meet the space and weight requirements of aircraft use. This additional superiority is the wide range of frequency selection available, accompanied by good spacing between active frequencies.

This chapter presents information relating to a representative communications equipment that will be operational during the time this training course is current. The primary objective is to introduce the equipment not as a revolutionary item but as an advancement in communications.

Inasmuch as a Service Instruction Manual exists for the equipment, no attempt at complete coverage is made. Some circuits that employ new or unusual concepts are treated in detail; however, these explanations do not replace the Service Instruction Manual approach, but only serve as supplementary material in presenting theory of operation.

UHF TRANSCEIVER AN/ARC-52

The transceiver described in this section is a representative example of military UHF communication equipment which meets the need in space-premium aircraft for increased effectiveness in smaller packages. It delivers substantially more power output than its predecessor, the AN/ARC-27. Also, it occupies only half as much space as the AN/ARC-27; has improved reliability, and is easier to maintain.

The ARC-52 is basically an AM radiotelephone system capable of operating on any one of 1,750 frequencies with 18 preset channels. Frequency selection is by automatic control. The channels are selected by a single control located remotely from the main unit.

The purpose of the equipment in an aircraft is to provide communication to ground stations, ships, or other aircraft. It operates in the range of 225 to 399.9 mc with a rated power output of 20 watts. The receiver is a double-conversion superheterodyne; two sources are employed for producing injection frequencies. A total of 36 crystals is required for full utilization of the 1,750 available frequencies, with common use of the crystals and many of the circuits for both transmission and reception.

In addition to regular two-way voice communication, the transceiver has the following facilities:

1. A fixed-tune guard receiver in the 238- to 248-mc range.

2. Tone-modulated signals between 920 and 1,120 cps for use as emergency or direction finding signals.

3. An output for operation in conjunction with UHF direction finder group.

MAJOR COMPONENTS

The physical appearance of the equipment is shown in figure 13-1, which illustrates the three basic components. The construction of the principal unit (the receiver-transmitter) and the control box is such that considerable

1023

The Anus

The anus is the external opening at the lower end of the digestive system. Except during defecation, it is kept closed by a strong muscular ring called the anal sphincter.

Accessory Organs of Digestion

The PANCREAS is a large, elongated gland lying posteriorly to the stomach. Its digestive juices, amylase, proteinase, and lipase are secreted through the pancreatic duct into the duodenum and act on all types of food. The pancreas contains a special group of cells called the Islands of Langerhans which secrete the hormone insulin, which is needed for the utilization of sugar by the body.

The LIVER is the largest gland in the body. It is located in the upper abdomen on the right side, just under the diaphragm and superior to the duodenum and pylorus.

Of its many functions the following are important to remember:

1. Metabolic. Metabolism of carbohydrates, fats, and proteins preparatory to their use or excretion.
2. Excretion. Formation and excretion of bile salts and pigment from bilirubin, a waste product of red blood cell destruction.
3. Storage of blood and water; and the products of carbohydrate, protein, and fat metabolism.
4. Detoxification of end products of protein digestion, and drugs; excess accumulation of certain hormones.
5. Protection. Production of antibodies and essential elements of the blood clotting mechanism.
6. Produces heat and forms vitamin A from carotin.

The GALLBLADDER is a sac usually stained dark green by the bile it contains, located in a hollow on the under side of the liver. Its duct, the cystic duct, joins the hepatic duct from the liver to form the common bile duct which enters the duodenum. The main function of the gallbladder is the storage and concentration of bile when not needed for digestion. In the absence of the gallbladder the common bile duct performs the same function.

Table 6-1.—Principal Digestive Juices, Source and Action.

Source	Digestive juice	Substance acted upon	Product
Salivary glands	Ptyalin	Starch	Complex sugar (Maltose)
Gastric glands	Hydrochloric acid (HCL) Pepsin	Pepsinogen Proteins	Pepsin Split proteins (proteoses, peptones)
Liver	Bile	Fats	Emulsified facts
Pancreas	Amylase	Starch	Complex sugar (maltose)
	Proteinases (trypsin, chymotrypsin)	Proteins, split proteins	Peptids, Polypeptids
	Lipase	Fats	Fatty acids, glycerol
Intestinal glands	Carbohydrases (maltase, sucrase, lactase)	Complex sugars (maltose, sucrose, lactose)	Simple sugars (glucose, fructose, galactose)
	Peptidases	Peptids, polypeptids	Amino acids
	Lipase	Fats	Fatty acids, glycerol

10254

CHAPTER 7

UROGENITAL SYSTEM

This chapter will discuss the urinary and genital systems. The urinary system is the primary filtering system of the body. It consists of the two glands, the kidneys, which produce urine; two tubes, the ureters, which drain the urine from the kidneys; a large reservoir, the bladder where urine is temporarily stored before it is excreted from the body; and a tube, the urethra, which carries the urine from the bladder to the outside of the body. All these parts, except length of urethra, are the same in both sexes.

KIDNEYS

The importance of the kidney can only be realized when its structure and function is understood. It is the only part of the urinary system in which any changes occur. The bladder, ureters, and urethra only store and pass the products of the kidneys.

The kidneys are two large, bean shaped organs designed to filter waste materials from the blood. They are located in the upper posterior part of the abdominal cavity, outside the peritoneal sac, one on each side of the spinal column. The upper end of each kidney reaches above the level of the 12th rib. The suprarenal gland (adrenal gland) sits like a cap on top of each kidney. Each kidney weighs about 4 to 6 ounces, measures about 4 1/2 x 2 x 1 1/2 inches, and is protected by a considerable amount of fat. Connective tissue and the peritoneum support the kidneys. Attached to the hollow side of each kidney is the dilated upper end of the ureter forming the kidney pelvis (fig. 7-1).

Structure

The kidney is comprised of two types of substances. The outside substance or cortex and the inner substance or medulla. Anatomically the cortex and medulla differ. The cortex or cortical substance is soft and granular in structure and reddish brown in color. The urine is formed in the cortex. The medulla or medullary substance is a pyramid shaped mass of tubes or tubules which drain the urine to the pelvis of the kidney.

Blood enters the kidney via the renal artery and is distributed to the glomerulus (fig. 7-2).

The glomerulus, lying in the cortex, consists of a tuft of capillaries. This tuft is surrounded by the glomerular capsule which is a cup-like dilation of the end of the renal tubule. This combination is called a Malpighian body.

The renal tubule begins with the malpighian body, takes multiple turns called the proximal convoluted tubule, extends toward the hilum in the medullary portion to form the descending loop of Henle, doubles back on itself as the ascending loop of Henle, and goes through several more turns as the distal convoluted tubule. The complete essential unit is called a nephron of which there are about one million in each kidney. For this reason a large portion of the kidney may be destroyed without serious body damage. Several of the nephrons terminate in one collection tubule.

Several collecting tubules unite to form a renal pyramid which drains the urine into a calyx of the kidney pelvis.

Function

The kidneys are effective blood purifiers, and fluid balance regulators. Along with maintaining a normal pH of the blood (acid-base balance), they keep the blood slightly alkaline by removing excess substances from the blood. For example: if the blood becomes too acid they will remove acid in the form of salts; if, on the other hand, the blood is too alkaline, they will remove alkaline salts.

The main function of the kidneys is to remove the nitrogenous waste products that result when

10255

Figure 7-1.—Cross section of the kidney.

products of protein are broken up. They also remove excess sugar.

Besides filtration, the second important function is reabsorption of water, salts, sugar, and protein elements of the blood. This selective reabsorption keeps the blood at an acid-base balance and also at a constant concentration of water, salts, and proteins. This delicate balance if necessary for normal life processes. Controlled reabsorption accounts for the amount of urine which is finally passed from the kidneys. The glomerulus filters gallons of blood each day. It is estimated that 10,000 quarts of blood pass through the kidneys in 24 hours and about 80 gallons of glomerular filtrate is formed. But all the water from this filtrate is reabsorbed in the renal tubules except that containing the concentrated waste products. The amount of urine excreted (micturition) by a normal person varies from 1000 to 1500 ml. per day. A person can get by if he only excretes 500 ml. per day.

Figure 7-2.—Functional unit of the kidney.

The amount of urine excreted varies greatly with temperature, water intake, and state of health. No matter how much water you drink the blood will always remain at a constant concentration, and the excess water will be excreted by the kidneys. A large water intake does not put a strain on the kidneys as one might think, instead it eases the load of concentration placed on the kidneys.

In blood plasma there is normally 0.03 percent of urea, while in the urine there is normally 67 times as much, or about 2 percent. This great increase is caused by the concentration of urea contained in a large kidney area in a relatively small quantity of urine.

Besides removing waste products normally found in the body, the kidneys also remove toxic substances such as certain barbituric acid derivatives, mercury, alcohol, and other drugs.

One of the familiar diseases associated with the kidneys is glomerulonephritis which is caused by protein loss from the body due to damaged glomeruli. Another disease, though not as prevalent, is uremia. This is caused when the kidneys fail to remove the waste products from the blood and they accumulate in high concentrations. This condition is serious and sometimes fatal.

URETERS

The ureters are two membranous tubes about the diameter of a goose quill (1/8 inch) and 15 to 18 inches long. Their only function is to carry urine from each kidney, down behind the peritoneal sac to the urinary bladder.

10256

BLADDER

The urinary bladder is a musculomembranous sac located in the pelvic girdle. It functions as reservoir for urine until it empties through the urethra.

URETHRA

The urethra is a membranous tube from the bladder to the exterior, ending in a meatus or opening. It conveys the urine and in the male, the secretions of the genital system to the outside. In the male it is about eight inches long and is divided into three parts, the prostatic, the membranous, and the penile portions. The prostatic urethra, about an inch in length, is surrounded by the prostate gland. It contains the orifices of the prostatic and ejaculatory ducts. In this section the urethra is the largest. The membranous urethra is about 1/2 inch long. The penile urethra is the longest and lies along the base of the penis, extending to its external opening the urinary meatus.

MALE REPRODUCTIVE SYSTEM

The male organs of reproduction are the penis and testes (testicles) with associated ducts and glands (fig. 7-3).

Figure 7-3.—The male reproductive system.

SCROTUM

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cord. Immediately underlying the skin is a thin layer of muscular fibers (cremaster) which is controlled by temperature, and contracts or relaxes to adjust the testes. This lowers or raises the testes in relation to the body, and is required because a temperature lower than the body temperature is required to bring the sperm cells to maturity.

TESTES

The testes are oval glands suspended by the spermatic cord in a pouch. They perform two functions: production of spermatozoa (sperm), and secretion of the male sex hormone, an endocrine substance.

Lying close to the superior pole of each testis is the epididymis, a ductal system that collects and transmits sperm form the testis.

SPERMATIC CORDS

The two spermatic cords, each of which suspends and supplies a testis, are formed by the ductus deferens, arteries, veins, lymphatics, and nerves, bound together by connective tissue.

DUCTUS DEFERENS (VAS DEFERENS)

The ductus deferens is a small tube which connects the epididymis and ejaculatory duct. It ascends as a part of the spermatic cord through the inguinal canal into the pelvic cavity and transmits the sperm to the ejaculatory duct.

SEMINAL VESICLES

The seminal vesicles are two pouches that lie between the bladder and the rectum. They secrete and store a fluid to be added to the secretion of the testes at the time of ejaculation.

EJACULATORY DUCT

The ductus deferens and the ducts from the seminal vesicles converge to form the short ejaculatory duct which leads into the prostatic urethra.

PENIS

The penis is composed of three cylindrical bodies of spongy cavernous tissue, bound together by connective tissue and loosely covered

10257 10256

by a layer of skin. Two of the bodies, corpora cavernosa, lie superiorly side by side; the third body, corpora spongiosum, is median, lying in the groove between the other two. The dilated distal end of the corpora spongiosum is known as the glans penis. The cavernous tissue becomes greatly distended with blood during sexual excitement causing erection of the penis. The loose skin of the penis folds back on itself at the distal end forming the prepuce, or foreskin and covers the glans. Frequently the prepuce is surgically removed (circumcision) to prevent irritation and facilitate cleanliness.

PROSTATE GLAND

This gland is made of smooth muscle and glandular tissue that surrounds the first part of the urethra. It resembles a chestnut in shape and size. It secretes an alkaline fluid to keep the sperm mobile and protect them from the acid secretion of the female vagina. This substance is discharged into the urethra as a part of the ejaculate or semen, during the sexual act.

BULBOURETHRAL GLANDS (COWPER'S GLANDS)

Cowper's glands are two pea-sized bodies, one on either side of the membranous urethra, the excretory ducts of which open into the urethra. They secrete a mucous-like alkaline fluid during the sexual act to provide lubrication.

SEMEN

The semen is made of sperm and secretions from the seminal vesicles, prostate, and cowper's glands. It is discharged as the ejaculate during sexual intercourse. There are millions of sperm cells in the semen of each ejaculation, but only one is needed to fertilize the ovum. It is generally considered that fertilization of the ovum occurs while it is still in the uterine tube. Therefore, it is apparent that sperm cells can move actively in the seminal fluid deposited in the vagina, and through the layers of the secretions lining the uterus and uterine tubes.

Although the prostate, seminal vesicles, and bulbourethral glands secrete most actively during sexual intercourse, a certain amount is being formed continously. During periods of prolonged sexual abstinence, discharge of this accumulation may occur spontaneously during sleep as a nocturnal emission or "wet dream". This is an entirely normal condition and does not represent a harmful or disease state; on the other hand, retention of these secretions in no way impairs health or the mental state.

At times, what appears to be semen may drip from the penis on straining to move the bowels. This is the secretion of the prostate and seminal vesicles being forced out by the increased pressure within the abdominal cavity and forceful passage of feces through the rectum which lies close to these structures. This occurrence does not indicate disease or infection, when urethral discharge is present only during such acts of straining. Any continuing discharge should be examined for evidence of infection.

FEMALE REPRODUCTIVE SYSTEM

The female reproductive system includes the ovaries, the uterine (fallopian) tubes, the uterus, the vagina, the external genitalia, and the mammary glands (fig. 7-4).

The essential female organs for reproduction are the ovaries and the uterus. The ovaries produce the ova, one of which normally matures each 28 days. The maturing of female sex cells, or ova, goes on for about 30 years of a woman's life, beginning between the ages of 10 and 15 and stopping between the ages of 40 and 50. The uterus provides a place where a fertilized ovum can be protected and nourished while it is developing into a fetus (unborn child). In making ready to receive and nourish an ovum, the lining of the uterus becomes swollen and soft and has much more blood in it than usual. If the ovum is not fertilized and the blood is not needed for its nourishment, then the excess blood and part of the swollen membrane sloughs off and is discharged from the uterus through the vagina in the form of a bloody discharge. This discharge ordinarily occurs every 28 days and is called menstruation.

OVARIES

The ovaries are two almond-shaped glands suspended by ligaments in the upper pelvic cavity, one on either side of the uterus. Their prime function is to produce the ova and the female hormones estrogen and progesterone. While those hormones are manufactured by the ovaries, their production is controlled by the anterior pituitary gland. These hormones play essential roles in development of secondary sex characteristics, the reproductive cycle, and gestation and lactation.

10258

10258

Each ovary normally releases an ovum each 56 days, the right and left ovary alternately discharging an ovum every 28 days. Menstruation in most women is therefore a 28-day cycle.

UTERINE TUBES (FALLOPIAN TUBES)

The uterine tubes convey the ova from the ovaries to the cavity in the uterus. These tubes are in contact with the ovaries but are not continuous with them. Their funnel-shaped openings, called free openings, are fringed with finger-like processes. The tubes terminate in the uterus. The precise mechanism by which the ovum is transported from the ovary to the uterine tube is unknown. Contraction of the muscle tissue and the finger-like processes surrounding the funnel-shaped end of the tube, probably effect the transfer. The fertilization of the ovum is believed to take place in the tube and the fertilized ovum is then normally passed on into the uterus.

UTERUS

The uterus is a hollow, pear-shaped organ with thick muscular walls. It is lined with a specialized epithelium called endometrium. It is the endometrium which undergoes partial destruction every 28 days in the nonpregnant woman.

Normally the uterus is about 7 centimeters long by 5 centimeters wide at its upper widest portion. It has three openings: the openings of the uterine tubes laterally, and the opening into the vagina. The parts of the uterus are the body, which is the large upper portion, and the cervix, which is the smaller portion that projects in the upper part of the vagina. The cervical opening into the vagina is called the external orifice.

Figure 7-4.—The female reproductive system.

VAGINA

The vagina is a muscular canal lined with mucus membrane which extends from the cervix to the vulva. The canal is about 7.5 centimeters long and its lining membrane, which is greatly folded, is continuous with the lining of the uterus. The vagina is the organ which receives the male sperm during intercourse. It also forms an important part of the birth canal, stretching widely during delivery.

VESTIBULAR GLANDS

The greater vestibular glands (Bartholin's glands) are the female counterpart of the male bulbourethral glands. They consist of two small, roundish bodies on either side of the vagina. Each gland opens by means of a long simple duct and secretes a fluid, cheifly mucus, between the hymen and labia minora.

EXTERNAL GENITALIA

The external genital organs, referred to collectively as the vulva, include the mons pubis, labia majora, labia minora, clitoris, vestibule, the lesser vestibular glands, and hymen. The mons pubis is the fat pad located anterior to the symphysis pubis. It is composed of a collection of fatty tissue beneath the skin and is covered with hair in the adult. The labia majora are two folds of skin extending from the mons pubis anteriorly to the anus posteriorly. Within these two folds of skin are two smaller folds called the labia minora or minor lips. The clitoris is a small body composed of erectile tissue located at the point where the two labia minors meet; the vestibule is the area between the labia minora into which the urethral and vaginal orifices open. The lesser vestibular glands are small mucous glands with ducts opening between the urethral and vaginal orifices. The hymen is a fold of mucous membrane which extends across the lower part of the vagina.

10259

MAMMARY GLANDS

The mammary glands or breasts are accessory organs of the female reproductive system. They secrete milk for the nourishment of the newborn infant, a process called lactation. The glands resemble sweat glands in structure. At the center on the ventral surface is a nipple with a rounded tip containing 15 or 20 depressions into which ducts from the lobes of the glands empty. During pregnancy, hormones secreted by the ovaries cause the glandular tissue to grow in preparation for lactation. At birth, hormones secreted by the anterior lobe of the pituitary gland stimulate production of milk in the glands which have been prepared by the ovarian hormones. Under average conditions, milk production continues for 6 to 9 months following delivery.

10260

CHAPTER 8

ELEMENTARY RULES FOR FIRST AID TO THE INJURED

FIRST AID is the emergency treatment of the sick or injured before regular medical or surgical attention can be obtained. It should neither supersede nor take the place of proper medical or surgical attention, and should consist of furnishing temporary assistance to a sufferer, pending the arrival of competent medical aid.

The purposes of first aid are:

1. To save life
2. To prevent further injury
3. To preserve resistance and vitality.

A real knowledge of first aid and its purposes, when properly applied, may mean the difference between life and death, between rapid recovery and long hospitalization, between temporary disability and permanent injury.

Knowing when to, what to, and how to apply first aid measures for the many and various conditions that confront the hospital corpsman in emergency requires a great deal of knowledge, and a continual, studious effort on his part to keep abreast of the changes in and of the newer concepts of first aid treatment.

MINOR SURGERY is that part of surgery that includes procedures not endangering life. It includes the application of bandages, splints, dressings, and sutures, counterirritation, cauterization, and similar simple surgical measures.

GENERAL PROCEDURES IN CASE OF INJURY

Observe the following rules:

1. DO NOT get excited. Take charge of the situation, act quickly but efficiently. Decide as soon as possible what has to be done and which one of the patient's injuries needs attention first.
2. DO NOT MOVE a patient until all possible first aid has been rendered.
3. DO NOT TOUCH open wounds or burns with your fingers or other objects. This may cause serious infections and may cost the patient his life.
4. DO NOT give an unconscious patient liquids.
5. KEEP the patient lying down on a flat surface until his injuries have been determined.
6. EXAMINE THE PATIENT for cessation of respiration, hemorrhage, traumatic injuries and evidence of poisoning. These conditions take precedence over everything else and demand immediate treatment.
7. REMOVE only enough clothing to get a clear idea of the extent of the injury. Preferably, rip the clothing along the seams, but cut if necessary. Removing clothing in the usual way may do great harm, especially in fractures. Do not remove unnecessary clothing; exposure to cold may precipitate the condition of shock.
8. KEEP the patient comfortable. This can be done while the patient's injuries are being cared for. A blanket over the patient may do him as much good as the dressing one applies to his wounds.
9. AVOID allowing the patient to see his injury. Assure him that his injuries are understood and that he will get good care.

ARTIFICIAL RESPIRATION

GENERAL

Breathing is an essential function of the human body. It must be maintained to prevent serious damage or death. When breathing stops, the rescuer must begin artificial respiration within a very few minutes and continue until:

1. Patient resumes regular breathing.
2. Patient is declared dead by competent authority.
3. There is no hope of recovery. (Estimated four hours or longer).

10260

10261

Before any method of artificial respiration can be effective, the following procedures must be completed:

1. Clear the mouth and throat of all obstructions. (mucous, froth, foreign bodies).

2. Place the patient in proper position for the method to be used.

3. When patient begins breathing, synchronize your efforts with his.

This text will discuss three of the many methods of artificial respiration.

MOUTH-TO-MOUTH

This method is the most practical for emergency treatment of an apneic individual of any age. It gives a far greater exchange of air and is easier to do. The proper technique is as follows:

1. Clear mouth and throat of patient. Wipe out obstructions with fingers or cloth.

2. Place patient in supine (face-up) position.

3. Kneel at patient's side facing the head.

4. Place fingers under angle of patient's chin, thumb in corner of his mouth. Lift the jaw upward.

5. Tilt head back and hyperextend the neck. This will open and align the air passage.

6. Pinch nostrils closed (except infant).

7. Place mouth over patient's mouth (for infant, place mouth over nose and mouth) and form tight seal with lips. Mouth must be wide open to completely seal the open mouth of the patient.

8. Blow (puff for infant), exhale firmly into patient's mouth until chest rises. If the chest does not rise, reposition the head and improve support of the lower jaw.

9. Remove mouth and inhale. During this period, rescuer should hear and feel the escape of air from the patient's lungs.

10. Repeat steps 8 and 9 (15-20) times per minute—20 times for children).

11. Remove air in patient's stomach. Periodically, between breaths, place hand over the pit of the stomach and press air out of the stomach.

12. To prevent dizziness, the rescuer should pause momentarily after each minute (15-20 breaths) and exhale normally. If dizziness persists, the rescuer is working too fast.

BACK-PRESSURE ARM-LIFT (HOLGER NEILSEN)

The back-pressure arm-lift technique is as follows:

1. Clear mouth and throat of patient. Wipe out obstructions with fingers or cloth.

2. Place patient in prone (face down) position.

3. Kneel on one knee or both knees at the patient's head, facing him.

4. Bend patient's elbow and place his hands one upon the other. Turn his face to one side, lift his jaw upward and toward you, and "hook" his jutting jaw over his hands (hyperextension of neck).

5. Place palms of your hands on patient's back, heels of hands lie just below a line running between the armpits, fingers pointing downward and outward.

6. Rock forward until arms are vertical, allowing the weight of the upper part of the body to exert slow, steady pressure downward on the hands. Keep the elbows straight.

7. Release the pressure, avoid a final thrust, and rock slowly backward, grasping the patient's arms just above the elbows and draw his arms toward you just enough to feel resistance in the patient's shoulders. Keep your elbows straight.

Figure 8-1.—Mouth-to-mouth artificial respiration.

10262

8. Rock forward, dropping patient's arms gently to the ground and repeat steps 6 and 7 (about 20 times a minute).

BACK-PRESSURE HIP-ROLL

The back-pressure hip-roll technique (useful when injuries prevent use of other methods) is as follows:

1. Prepare patient in same manner as for back-pressure arm-lift method.

2. Kneel on one knee astride the patient's thighs, facing toward the head, place the palms of your hands on the lower part of the rib cage, the little finger touching the lowest rib and the ends of the fingers just out of sight.

3. Rock slowly forward, keeping the arms straight, allowing the weight of the upper body to force expiration. At the end of the rock, the rescuer's shoulders should be directly over the heels of the hands.

4. Then quickly bring the hands back along the sides of the patient to the hips, grasping the hips and pulling upward in a single motion. At the end of the upward motion the hips are released and the operator goes back to his original position. This procedure is completed about 20 times a minute.

Figure 8-2.—Back pressure-arm lift artificial respiration.

10263

1. Receiver-transmitter.

3. Mounting MT-1477.

Figure 13-1.—Major components of AN/ARC-52.

reduction in weight and size has been made compared with comparable equipments. Weighing 52.5 pounds, including mount and controls the transceiver occupies only 1.08 cubic feet. Thus, it is smaller and lighter than many multichannel UHF sets now in use; many of which have no provisions for pressurization. The latter feature, together with cooling equipment, permits operation at altitudes up to 70,000 feet.

MODULAR UNITS

The ARC-52 is designed from a modular building block approach. As indicated in figure 13-2, the set is made up of 13 subassemblies or modules; these plug into the main chassis. The modules conform in size to a standard of 4 1/2 by 4 1/2 by 1 1/2 inches or some multiple thereof. Besides facilitating maintenance and enabling certain economies in engineering, production, and stocking, modular design provides great flexibility in packaging to adapt the equipment shape to specific aircraft. This feature makes the set especially applicable to communication-navigation-identification (CNI) systems, such as the AN/ASQ-19, AN/ASQ-56, AN/ASQ-57, and AN/ASQ-58.

The modules are shown separately in figure 13-2 with the completed assembly appearing in the center. Reading from left to right in the front row, the units are as follows: guard receiver, audio amplifier, spectrum generator, receiver RF amplifier and transmitter preamplifier, power amplifier, and a-c power supply. Those in the back row are the fixed IF subassembly (1.85 mc), variable IF subassembly (20-30 mc), oscillator, mechanical tuner, modulator, relay, and rectifier.

A major advantage of the type of construction employed is the ease with which the equipment may be modified. Versions of the set have been designed to function with various types of a-c/d-c primary power supply combinations. Modification of other circuitry in the equipment can be accomplished similarly, with module replacement simplifying the logistics problem when the equipments are dispersed over widely separated areas.

The problem of mechanical coupling between modules for tuning functions is solved by connecting the mechanical drive assembly with the appropriate modules by means of a gear-plate assembly mounted underneath the chassis. Any change in the modules involved or their arrangement can be easily accomplished by simple configuration changes in the gear plate. The modules have quick disconnect mechanical couplers. Captive central elements in the couplers make removal and replacement of the module relatively simple with no synchronization problems.

In maintenance, the modular concept permits rapid replacement of defective subassemblies, which increases equipment availability. Troubleshooting is comparatively easy because of the modular breakdown and the provision of readily accessible test points.

Ease of maintenance has been one of the principal considerations in the development of UHF transceiver equipment. The objective is to permit thorough servicing with a minimum of test equipment. After removal from the transceiver, most of the modules can be operated by the use of extension cords and maintenance fixtures which enable operation and servicing of those subassemblies that require mechanical interconnection.

OPERATIONAL PROCEDURES

The operator has fingertip selection of any of the 1,750 available frequencies. Any of 18

1024 SSUI

Place hands for back-pressure.

Rock forward and press back.

Roll subject onto operator's thigh or knee. (front view and side view)

Figure 8-3.—Back pressure-hip roll artificial respiration.

CONTROL OF HEMORRHAGE

GENERAL

In the care of the wounded, control of active bleeding must be considered most urgent. Hemorrhage, or bleeding, is the escape of blood from arteries, veins, and capillaries through a break in their walls.

The average adult body contains about six quarts of blood. One pint can usually be lost with no harmful effects. The rapid loss of one quart of blood may produce symptoms:

1. Pale skin or pale mucous membrane. Skin moist and clammy or waxy.
2. Temperature subnormal.
3. Pulse rate increased. Pulse feeble and easily compressible or lost.
4. Blood pressure lowered.
5. Pupils of eyes dilated and slow in reacting to light or in accommodation.
6. Tinnitus (ringing in ears).
7. Faintness or actual fainting (syncope) may be the first symptom of internal hemorrhage.
8. Dehydration, frequent complaints of thirst.
9. Air hunger, often with yawning.
10. Impaired vision, especially in the erect or sitting position.

The greater the loss of blood the more profound the symptoms. The loss of 25 percent of blood volume is dangerous; the loss of one-half the blood volume is usually fatal. The symptoms are indicative of both external and internal bleeding and are easily confused with the symptoms of shock.

TREATMENT OF EXTERNAL BLEEDING

ARTERIAL BLEEDING.—Blood is bright red, gushes forth in spurts which are synchronized with the pulse. This will drain the patient's blood in a very short time. To control the bleeding, apply:

Figure 8-4.—Pressure points.

10265

1. DIGITAL PRESSURE as illustrated in figure 8-4 followed by elevation of the part and:

2. Application of a firm pressure dressing may impede other circulation if too tight. Remember, control of bleeding by pressure takes a little time. Do not become alarmed; a little persistance with pressure will accomplish the purpose. The pressure should be maintained while someone else brings sufficient sterile gauze or compresses to pack firmly and directly into the wound. A compress should then be applied over the wound and direct, steady, and sustained hand pressure applied while it is snugly bandaged in place. Snug as opposed to tight bandaging cannot be stressed too much. In most instances of serious bleeding this procedure is the best of all methods and will almost always eliminate the need for a tourniquet. Get the patient under professional medical care as soon as possible.

VENOUS BLEEDING.—Blood is dark red and escapes in a steady flow. This is not as apparent as arterial bleeding, but it is more dangerous for that reason.

Venous bleeding is almost always controlled by pressure. In most cases application of a dressing and a snug bandage over the dressing will suffice. In more profuse bleeding, the extremity may be snugly bandaged from the toes or fingers up to the bleeding point after elevation of the part.

CAPILLARY BLEEDING.—Blood is intermediate in color and oozes from the wound. It can be controlled with a sterile compress and a bandage.

TREATMENT OF INTERNAL BLEEDING

Internal hemorrhage can be controlled only by surgery. Until the patient reaches a hospital he must be kept alive by transfusions of whole blood or by blood volume expanders. Keep the patient quiet and reassured.

Figure 8-5.—Spiral bandage for control of bleeding.

Figure 8-6.—Look for symptoms in shock.

Hemorrhage may be started spontaneously (by straining, coughing and hypertension) or result from trauma (by cutting, crushing, or tearing of body tissue.

SHOCK

Shock is a poorly understood physiological depression of the body's vital processes and is present to a greater or lesser degree in all injuries. It is chiefly nervous in origin and effects a failure in blood circulation with resultant impairment of all vital organs. By and large, the more extensive the injury, the more profound the shock picture will be.

All injured persons are subject to shock in varying degrees. It may be present at the time of injury or develop hours later. Therefore, all injury cases must be observed and treated for shock, should it occur.

SIGNS AND SYMPTOMS

1. Breathing may be normal, rapid or labored.
2. The lips may be pale or cyanotic (bluish gray).
3. The skin may be pale or ashen gray.
4. The skin temperature may be lowered and the body covered with clammy sweat.
5. The pulse may be rapid, weak, thready, and of poor volume.
6. The blood pressure usually falls in shock.
7. There may be retching, nausea, vomiting, hiccups and dryness of mouth, lips, and tongue.
8. Restlessness, apprehension, and then apathy are usual symptoms.
9. Frequent complaints of thirst.

TREATMENT

The first aid treatment of shock is primarily prevention. The patient should be placed in a supine position, with head lowered and feet elevated to encourage return of blood to the heart and a generous supply to the brain. Chest or head injuries should be positioned with the head slightly elevated. If face, jaw, mouth, or throat injuries produce bleeding into the pharynx, it is imperative that the patient be placed in a prone position with the head turned to one side and lowered 1/2 to 1 foot. Keep the patient warm with blankets. Treat the cause of the shock. If bleeding is present it must be stopped. If pain is present, its alleviation is an important part of the treatment. When symptoms of shock persist despite these measures, more expert medical assistance must be obtained.

10267

CHAPTER 9

BANDAGES, SPLINTS AND FIRST AID MATERIALS

SPLINTS

SPLINTS are used to immobilize a fractured part. There are two general classifications: traction splints and coaptation splints (fig. 9-1).

TRACTION SPLINTS of which the Thomas splint is a well known example, serve to immobilize the limb, resting it in a trough. Most importantly, however, they have a feature that provides for a pulling action (traction) preventing overriding of bone fragments. A Spanish windlass permits application of traction at the narrow end of the splint, while the ring at the wider end provides counter-traction. Many adaptations of the Thomas splint have been made which use the general principle of traction and counter-traction, for example, the Murray-Jones humerus splint. Traction splints are indicated in fractures where there is much muscle pull, tending to displace the fragments.

Now available is an adjustable canvas splint called a "universal" splint. It has parts to make it adaptable for leg, arm, back, and neck. The package contains a leg splint, an outrigger which is adjustable for length, plus two padded wire mesh splints.

COAPTATION SPLINTS are those which are used solely to immobilize the fracture. The most common type used are basswood splints and are conveniently packaged in varying sizes; they are held about the limb by means of roller bandages, cravat bandages, or any material available as handkerchiefs, rope, clothing, adhesive tape. When basswood splints are not available, canes, rifles, sticks, stiff wire or folded blankets may be used to support the broken bones.

Generally, coaptation splints should be long enough to reach the joints above and below the fracture; they should be wide enough to prevent pinching; and they should be padded except perhaps, when applied over thick clothing. Padding may be cotton, clean rags, grass, moss, or pieces of blankets or clothing. An assistant should be sought to support the limb during application to prevent excessive motion at the fracture site.

While splints should be applied snugly, care should be taken not to apply them too tightly for fear of cutting off blood circulation; leave tips of the fingers and toes exposed. Plaster of paris can be used for splinting purposes, but it is best to leave its application to the Medical Officer.

BANDAGES AND BANDAGING

Bandages are used to hold dressings applied to the surface of the body, to secure splints used in treatment of fractures and dislocations, to create pressure, and to immobilize joints. Various materials are employed such as gauze, flannel, muslin, linen, and elastic webbing. Gauze is used frequently because it is light, soft, thin, porous, readily adjusted and easily applied. Muslin is also used frequently since it is inexpensive and universally available.

A hospital corpsman should be familiar with the general rules of bandaging and proficient in the application of various types of bandages. The comfort of the patient, the security of the dressing, and the professional reputation of the corpsman depends upon the proper application of a bandage, since an untidy, uncomfortable, insecure bandage can only result in adverse criticism.

TRIANGULAR BANDAGES

TRIANGULAR BANDAGES are usually made of muslin. They are made by cutting a 36" to 40" square on a piece of cloth, and then cutting the square diagonally, thus making two triangular bandages (in sterile packs on Navy's medical stock list). A smaller bandage of this kind may

10268

Figure 9-1.—Thomas splint for traction; type of coaptation splint.

be made by folding a large handkerchief diagonally. The longest side of the triangular bandage is called the base; the corner directly opposite the middle of the base is called the point; and the other two corners are called ends (fig. 9-2).

The triangular bandage is useful because it can be folded in a variety of ways to fit almost any part of the body. Padding may be added to areas that may become uncomfortable.

TRIANGULAR BANDAGE OF THE HEAD

This bandage is used to retain dressings on the forehead or scalp. Fold back the base about two inches, thus making a hem. Place the middle of the base on the forehead, just above the eyebrows, with hem on the outside. Let the point fall over the head and down over the occiput (back of the head). Bring the ends of the triangle around the back of the head above the ears, cross them over the point, carry them around to the forehead and tie in a SQUARE KNOT. Hold the dressing firm with one hand and, with the other, gently pull down the point until the dressing is snug; then bring the point

Figure 9-2.—Triangular bandage.

up and tuck it over and in the bandage where it crosses the occiput (fig. 9-3).

TRIANGULAR BANDAGE FOR SHOULDER

Cut or tear the point, perpendicular to the base, about ten inches. Tie the two points loosely around the patient's neck, allowing the base to drape down over the dressing on the injured side. Fold the base to the desired width, grasp the ends, and fold or roll the sides toward the shoulder to store the excess bandage. Wrap the ends snugly around the upper arm, and tie on the outside surface of the arm (fig. 9-4).

TRIANGULAR BANDAGE FOR CHEST

Cut or tear the point, perpendicular to the base, about ten inches. Tie the two points loosely around the patient's neck, allowing the

Figure 9-3.—Triangular bandage for head.

10269

Figure 9-4.—Triangular bandage for shoulder.

10270

bandage to drape down over the chest. Fold the bandage to the desired width, carry the ends around to the back, and secure by tying (fig. 9-5).

TRIANGULAR BANDAGE FOR HIP OR BUTTOCK

Cut or tear the point, perpendicular to the base, about ten inches. Tie the two points around the thigh on the injured side. Lift the base up to the waist line, fold to the desired width, grasp the ends, fold or roll the sides to store the excess bandage, carry the ends around the waist and tie on the opposite side of the body (fig. 9-6).

Figure 9-5.—Triangular bandage for chest.

TRIANGULAR BANDAGE FOR SIDE OF CHEST

Cut or tear the point, perpendicular to the base, about ten inches. Place the bandage, points up, under the arm on the injured side. Tie the two points on top of the shoulder. Fold the base to the desired width, carry the ends around the chest and tie on the opposite side (fig. 9-7).

TRIANGULAR BANDAGE FOR FOOT

This bandage is used to retain large dressings on the foot. After the dressings are applied, place foot in center of a triangular bandage and carry the point over the ends of the toes and over the upper side of the foot to the ankle. Fold in excess bandage at the side of the foot, cross the ends, and tie in a square knot in front (fig. 9-8).

TRIANGULAR BANDAGE FOR HAND

This is used to retain large dressings on the hand. After the dressings are applied, place the base of the triangle well up on the palmar surface of the wrist. Carry the point over the ends of the fingers and back of the hand well up on the wrist. Fold the excess bandage at the sides of the hand, cross the ends around the wrist, and tie in a square knot in front (fig. 9-8).

CRAVAT BANDAGE

To make a cravat bandage, bring the point of the triangular bandage to the middle of the base and continue to fold until the desired width is obtained (fig. 9-9).

CRAVAT BANDAGE FOR HEAD

This bandage is very useful to control bleeding from wounds of the scalp or forehead. After placing the dressing over the wound, place the center of the cravat over the dressing and carry the ends around to the opposite side; cross them

10271

Figure 9-6.—Triangular bandage for hip or buttock.

Figure 9-7.—Triangular bandage for side of chest.

and continue to carry them around to the starting point and tie in a square knot.

CRAVAT BANDAGE FOR EYE

After applying a dressing to the affected eye, place the center of the cravat over the dressing

10272

Figure 9-8.—Triangular bandage for foot or hand.

Figure 9-9.—Cravat bandage.

Figure 9-10.—Cravat bandage for the eye.

and on a slant so that the lower end is inclined downward. Bring the lower end around under the ear of the injured side and the other end over the ear on the opposite side. Cross the ends in back of the head; bring them forward and tie them over the dressing (fig. 9-10).

CRAVAT BANDAGE FOR TEMPLE CHEEK OR EAR

After the dressing is applied to the wound, place the center of the cravat over it and hold one end over the top of the head, carry the other under the jaw and up the opposite side, over the top of the head, and cross them at right angles over the temple on the injured side. Continue one end around over the forehead and the other around the back of the head to meet over the temple on the injured side. Tie ends in square knot (fig. 9-11).

CRAVAT BANDAGE FOR ELBOW OR KNEE

After applying the dressing, and, if the injury or pain is not too severe, bend elbow or knee to

10273

Figure 13-2. —AN/ARC-52 modules arrayed about complete radio set.

preset channels or the guard channel may be selected by rotating a single channel selector control on Radio Set Control C-1607/ARC-52, shown in figure 13-1. Other frequencies may be chosen by rotation of four manual frequency controls until the desired frequency appears on the indicator dials.

The operator also has a volume control, and a function switch which enables him to turn the equipment on and select the following functions: transceiver only, transceiver plus guard receiver, and automatic direction finder.

Another feature which simplifies the operation of the equipment is a signal-to-noise squelch system. It also has carrier-squelch provisions. The squelch circuits are disabled on the basis of the signal-to-noise ratio (understandability) instead of solely on the level of the incoming carrier wave. This eliminates the need for the operator to adjust the RF gain squelch control.

TUNING SYSTEM

Tuning is accomplished automatically by means of autopositioners and associated electrical and mechanical components. The autopositioners are motor-driven units which adjust the tuning circuits and switches of the subassemblies in the receiver-transmitter. Autopositioner tuning action is controlled by the open-circuit seeking system, the basic principle of which is shown by the diagram in figure 13-3.

When the selector switch on the left and the seeking switch are set symmetrically, or with corresponding contacts occupying similar positions, there is no current path from the relay coil to ground. In this condition, the relay remains deenergized and the motor does not run.

When the selector switch is set to a position different from that of the corresponding seeking switch, the motor relay is energized

1025 1028

Figure 9-11.—Cravat bandage for the temple, cheek, or ear.

a right angle position before applying the bandage. Place the middle of a rather wide cravat over the point of the elbow or knee, and carry the upper end around the upper part of the elbow or knee, bringing it back to the hollow, and the lower end entirely around the lower part, bringing it back to the hollow. See that the bandage is smooth and fits snug, then tie in a square knot outside of the hollow (fig. 9-12).

CRAVAT BANDAGE FOR ARM OR LEG

The width of the cravat to use will depend upon the extent and area of the injury. For a small area, place the dressing over the wound and center the cravat bandage over the dressing. Bring the ends around in back, cross them and tie over the dressing. For a small extremity it may be necessary to make several turns around in order to use all the bandage for tying. If the wound covers a larger area, hold one end of the bandage above the dressing and wind the other end spirally downward across the dressing, until it is secure, then upward and around again and tie a knot where both ends meet (fig. 9-13).

CRAVAT BANDAGE FOR AXILLA (ARMPIT)

This cravat is to hold dressings in the axilla. It is similar to the bandage used to control bleeding from the axilla. Place the center of the bandage in the axilla over the dressing, and carry the ends up over the top of the shoulder and cross them. Continue across the back and the chest, to the opposite axilla and tie them. Do not tie too tight or the axillary artery will be compressed, adversely affecting the circulation in the arm (fig. 9-14).

CRAVAT BANDAGE FOR SPRAINED ANKLE

Do not remove the shoe when applying this bandage. Leaving it on will afford partial support. If the top of the shoe is above the ankle, loosen the laces to allow for swelling. Use a narrow cravat, and begin by placing the middle of the bandage under the instep. Carry the ends back and upward, crossing above and behind the heel and around forward crossing over the instep. Continue downward and backward this time close to the angle and under the first turn. Make a hitch and bring the ends forward, then around the ankle once more and tie over the instep (fig. 9-15).

ROLLER BANDAGE

In applying a roller bandage, the roll should be held in the right hand, so that the loose end is on the bottom; the outside surface of the loose or initial end is next applied to and held on the part by the left hand. The roll is then passed around the part by the right hand, which controls the tension and application of the bandage. Two or three of the initial turns of a roller bandage should overlie each other in order to secure the bandage and keep it in place. (See fig. 9-16.)

In applying the turns of the bandage, it is often necessary to transfer the roll from one hand to the other. Bandages should be applied evenly, firmly, and not too tightly. Excessive pressure may cause interference with the circulation and may lead to disastrous consequences. In bandaging an extremity, it is, therefore, advisable to leave the fingers or toes exposed in order that the circulation of these parts may be readily observed. It is likewise

510274

Figure 9-12.—Cravat bandage for the elbow.

Figure 9-13.—Cravat bandage for the arm, forearm, leg, or thigh.

safer to apply a large number of turns of a bandage, rather than to depend upon a few too firmly applied turns to secure a splint or dressing.

In applying a wet dressing, or one that may become wet, it is necessary to allow for shrinkage. The turns of a bandage should completely cover the skin, as any uncovered areas of skin may become pinched between the turns, with resulting discomfort.

In bandaging an extremity, it is advisable to include the whole member (arm or leg, excepting the fingers or toes) in order that uniform pressure may be maintained throughout. It is also desirable in bandaging a limb, that the part be placed in a position it will occupy when the dressing is finally completed, as variations in flexion and extension of the part will cause changes in the pressure of certain parts of the bandage.

The initial turns of a bandage of an extremity (including spica bandages of the hip and shoulder) should be applied securely, and when possible, around the part of the limb that has the smallest circumference. Thus, in bandaging the arm or hand, the initial turns usually are applied around the wrist, and in bandaging the leg or foot, the

720275

Figure 9-14.—Cravat bandage for the axilla.

Figure 9-15.—Cravat bandage for a sprained ankle.

the wrist, and in bandaging the leg or foot, the initial turns are applied immediately above the ankle.

The final turns of a completed bandage usually are secured in the same manner as are the initial turns, by the employment of two or more overlying circular turns. As both edges

Figure 9-16.—Anchoring a bandage about the wrist.

of the final circular turns are necessarily exposed, they should be folded under to present a neat, cuff-like appearance. The terminal end of the completed bandage is turned under and secured to the final turns by either a safety pin or adhesive tape. When these are not available, the end of the bandage may be split lengthwise for several inches, and the two resulting tails secured around the part by tying.

ROLLER BANDAGE FOR ELBOW

A spica or figure-of-eight type of bandage is used around the elbow joint to retain dressing in the region of the elbow and to allow a certain amount of movement. Flex the elbow slightly, if you can do so without causing further pain or injury, and anchor a 2 or 3 inch bandage above the elbow with two circular turns. Carry it diagonally downward across the hollow of the elbow, and encircle the forearm below the elbow with a circular turn. Continue the bandage upward across the hollow of the elbow to where you started. Make another circular turn around the upper arm, carry it downward, repeating the figure-of-eight procedure, and gradually ascend

10276

the arm. Overlap each previous turn about two-thirds of the width of the bandage. Secure the bandage with two circular turns above the elbow and tie. To secure dressings on the tip of the elbow, reverse the procedure and cross the bandage in the back (fig. 9-17).

Figure 9-17.—Roller bandage for the elbow.

ROLLER BANDAGE FOR HAND AND WRIST

For the hand and wrist a figure-of-eight bandage is ideal. Anchor the dressing, whether it be on the hand or wrist, with several turns of a 2 or 3 inch bandage. If on the hand, anchor the dressing with several turns and continue the bandage diagonally upward and around the wrist and back over the palm. Make as many turns as necessary to secure the dressing properly (fig. 9-18).

ROLLER BANDAGE FOR ANKLE AND FOOT

The figure-of-eight bandage is also used for dressings of the ankle, as well as for supporting a sprain. While keeping the foot at a right angle, start a 3 inch bandage around the instep for several turns to anchor it. Carry the bandage upward over the instep and around behind the ankle, forward and again across the instep and down under the arch, thus completing one figure-of-eight. Continue the figure-of-eight turns, overlapping one-third to one-half its width, with an occasional turn around the ankle, until the dressing is secure or until adequate support is obtained. (See fig. 9-19.)

Figure 9-18.—Roller bandage for the hand and wrist.

Figure 9-19.—Roller bandage for the ankle and foot.

ROLLER BANDAGE FOR HEEL

The heel is one of the most difficult parts of the body to bandage. Place the free end of the bandage on the outer part of the ankle and bring the bandage under the foot and up. Then carry the bandage over the instep, around the heel and back over the instep to the starting point. Overlap the lower border of the first loop around the heel and then repeat the turn, overlapping the upper border of the loop around the heel. Continue this procedure until the desired number of turns is obtained and secure with several turns around the lower leg (fig. 9-20).

10277

Figure 9-20.—Roller bandage for the heel.

Figure 9-21.—Spiral reverse bandage for the forearm.

ROLLER BANDAGE FOR ARM AND LEG

The spiral reverse bandage must be used to cover wounds of the arms and legs; only such bandages can keep the dressing flat and even. Make two or three circular turns around the lower and smaller part of the limb to anchor the bandage and start upward, going around and around, overlapping about one-third to one-half the width of the previous turn. Continue as long as each turn lies flat. When the edge of a turn is loose, it is necessary to use the reverse lap. Continue the spiral, making the reverse laps when necessary, and secure the end when completed. Note that it is not necessary to reverse each turn as described in most text books. (See fig. 9-21.)

BARTON BANDAGE

With the initial end of the bandage applied to the head, just behind the right mastoid process, the bandage is carried under the bony prominence at the back of the head, upward and forward back of the left ear, obliquely across the top of the head, downward in front of the right ear, under the chin, upward in front of the left ear, obliquely across the top of the head, crossing the first turn in the midline of the head, thence backward and downward to the point of origin behind the right mastoid. Then it is carried around the back of the head under the left ear, around the front of the chin, and under the right ear to the point of origin. This procedure is repeated several times, each turn exactly overlying the preceding turn. The bandage is secured with a pin or strip of adhesive tape at the crossing on top of the head.

USES.—Fracture of the lower jaw and retention of dressings of the chin (fig. 9-22).

Figure 9-22.—The Barton Bandage.

10278

Figure 9-23.—Battle dressing.

BATTLE DRESSINGS

A BATTLE DRESSING is a combination of a dressing and bandage in one unit. It is made of many layers of gauze sewed to a muslin strip or strips. Each unit is stored in a sterile package, and is ready for instant use.

The uses of this item are limited only by the imagination of the user: in the field it ranges from minor wounds to splinting material for fractures.

CARE must be exercised in using this item:

1. Select the correct size for the job (small, medium and large).
2. Remove the outer package.
3. Tear off the sealed wrapper. Unfold and hold the dressing without touching the surface that will touch the wound.
4. Apply the sterile surface to the wound; wrap the bandage tails around the part, and secure by pinning or tying (fig. 9-23).

TRANSPORTATION

The ARMY LITTER is made essentially of canvas and is supported by wooden or aluminum poles. It is collapsible and is most practical for use in the field. (See fig. 9-24.)

Figure 9-24.—Army litter.

The STOKES STRETCHER is most commonly used for transportation of sick and injured personnel. It is essentially a wire basket supported by iron or aluminum rods (fig. 9-25). It is adaptable to a variety of uses since the patient

Figure 9-25.—Stokes stretcher.

1027 1501

Figure 9-26.—Neil Robertson stretcher.

can be held securely in place even if the stretcher must be tipped or turned. It is frequently used aboard ship, and is particularly valuable for transferring injured persons to and from boats. It can be used to rescue injured survivors from the water. It is also used for direct ship-to-ship transfer of injured persons. The Stokes stretcher should be padded with three blankets; two of them should be placed lengthwise, so that one will be under each of the patient's legs, and the third should be folded in half and placed in the upper part of the stretcher to protect the patient's head and shoulders. The patient should be lowered gently into the stretcher, and made as comfortable as possible. His feet must be fastened to the end of the stretcher so that he will not slide up or down. Another blanket (or more) should be used to cover him. The patient must be fastened by means of the straps which go over his chest, hips, and knees. Note that the straps go OVER the blanket or other covering, and thus hold it in place.

The NEIL ROBERTSON STRETCHER is specially designed for the purpose of removing casualties from engineroom spaces, holds, and other compartments where access hatches are too small to permit the use of regular stretchers. It is made of semi-rigid canvas; when firmly wrapped around the patient, mummy-fashion, it gives sufficient support so that the patient may be lifted vertically (fig. 9-26). Stretchers of this type can be made up on board ship or ordered from the Navy medical stock list and kept in appropriate places, ready for use. If no such stretcher is available when needed, a piece of heavy canvas wrapped firmly around the patient will serve somewhat the same purpose as the Neil Robertson stretcher.

OTHER METHODS OF TRANSPORTATION

When a patient must be moved and the stretchers are not available, it becomes necessary to improvise. Inherent in this problem of moving the injured is the strength required for one man to carry or drag another. Under favorable circumstances, the maximum distance one man can be expected to move a helpless individual is about 150 feet; and when the injured is larger than the rescuer, moving him any distance at all is a feat of strength. The illustrations in figure 9-27 will help in deciding the proper method of transportation for the patient.

10283 10283

Figure 13-3. —Basic simplified automatic positioning system.

and the motor is started. The motor continues to run until the seeking switch, which is repositioned by the motor, reaches a setting corresponding to that of the selector switch. This arrangement stops the motor by opening the relay circuit.

A simplified functional diagram of an autopositioner unit is shown in figure 13-4 which indicates the elements controlled by the open-circuit seeking system. The principal involved are a motor with a gear reduction train, a slip clutch, a rotary shaft to which is fastened a notched stop wheel, a pawl which engages the notches of the stop wheel, a relay for operating the pawl and controlling the motor, and a set of electrical contacts comprising the control system.

The autopositioner (fig. 13-4) performs the following sequence during the cycle of operation:

1. The system is at rest when the selector and seeking switches are in corresponding positions. The operator begins the cycle of frequency selection by adjusting the setting of the frequency selector knob.

2. The relay is energized, lifting the pawl out of the stop wheel and closing the motor contacts, thereby starting the motor.

3. The motor drives the autopositioner shaft and the rotor of the seeking switch until a position corresponding to the new position of the selector switch is reached. Rotation of the motor shaft sets various switches and tuning elements in the receiver-transmitter.

4. When the setting corresponding to the selector knob position is reached, the open-circuit seeking switch corresponds to the selector switch. The relay circuit is then opened, the pawl engages the stop wheel and the control shaft is brought to a quick stop. The motor coasts to a stop, dissipating the kinetic energy in the slipping clutch.

A diagram of the mechanical linkage in the tuning system of the receiver-transmitter is shown in figure 13-5. The drawing reveals the various tuners and switches which rotate during the operation of frequency selection. The average time required for the equipment to set up to frequency is between three and four seconds.

POWER REQUIREMENT

The physical construction of the ARC-52 is of interest since it illustrates general design features which are effective in attaining improved reliability, a quality of prime importance in airborne equipment. The subassembly method of packaging and the use of miniaturized parts not only permit small size and weight but also facilitates maintenance on a subassembly substitution basis. The power requirements of the equipment are relatively low; when transmitting, it draws 375 volt-amperes, a reduction of about 20 percent of

CHAPTER 10

PRINCIPLES OF NURSING

ORIENTATION TO NURSING PROCEDURES

Nursing in its broadest sense may be defined as an art and a science which involves the body, mind, and spirit of the patient. It promotes the patient's spiritual, mental, and physical health by teaching and by example. In its highest form, nursing calls for the outstanding qualities that are found in most persons who work successfully in other professional fields; sensitiveness to people and their moods, insight into human nature, an ability to distinguish what is true from what is false, the capacity for sustained effort, and the mastery of the techniques involved.

The scope of the material presented in this nursing chapter is limited to those activities which the corpsman will most likely encounter in a sick bay or hospital ward. It is further limited to the "how" and "what" to do and the reader is referred to other sections of the book for the "whys." In this manner it is hoped that the corpsman will more readily see the relationship of sections to one another and thus obtain the maximum benefit and use from this book.

This chapter was compiled with these objectives in mind:

1. To provide the corpsman with a guide for use in the care of his patient.
2. To provide a basis for the standardization of routine nursing procedures in Naval hospitals.

In attempting to attain these objetives, the text is presented in the form of procedures wherever possible.

The elements of care required for all patients are included in detail, while the care of patients with specific conditions is omitted or very limited. The ward management procedures included may be generally applied to all wards.

Nursing, as defined in this book, is the care given to sick and injured people. Nursing procedures are methods used in giving nursing care to these patients.

Purposes

The purposes of nursing and nursing procedures are as follows:

1. To maintain, promote, and restore the patient's health.
2. To prevent the patient from contracting a secondary infection or a complication.
3. To assist in the treatment of a patient with disease or abnormal condition.

To achieve these purposes, it is necessary that the corpsman:

1. Attend to the comfort of the patient.
2. Prevent the spread of infection.
3. Assist with or perform diagnotic and therapeutic procedures as ordered by the doctor.
4. Plan and adapt the nursing care to meet the needs of his patient.

The Comfort of the Patient

Providing for the comfort of a patient requires attention to both the physical and mental state of the patient. By attention is meant the accurate observation of the patient's needs and then doing something about them.

"Make the patient comfortable" is NOT ordered by the doctor; it is up to the corpsman. Making the patient physically comfortable includes providing facilities for a clean patient in clean surroudings; frequent change of position, employing comfort devices when needed; relieving the patient of pain in so far as possible and attention to the patient's diet and elimination.

The bed, when neatly and correctly made, is a most important factor in the comfort of a patient. In promoting the physical comfort of a patient, it should be remembered that his mental attitude has a marked influence on his

10284

physical condition. Making the patient mentally comfortable includes keeping the ward quiet and cheerful; providing for the patient's rest and relaxation; treating the patient as a person; promoting his confidence in ward personnel; and keeping him contented. Physical and mental comfort depend on each other; both must be considered and remembered when planning a patient's care.

Prevent the Spread of Infection

The patient comes to the hospital or sick bay expecting to be relieved of his complaints. Everything done for the patient must be directed toward relieving his complaints without exposing him to a new infection or causing a new abnormality or disease.

All people are possible carriers and all people are possible victims of disease caused by living organisms. Remember! You are people! That is the reason why you are urged to get enough sleep and rest, why you are told to keep your body and clothes clean, and why washing your hands will be stressed throughout this section.

The comfort of the patient and the prevention of the spread of infection are measures required by and for all patients and therefore, are considered as basic nursing care.

CORPSMAN-NURSE-DOCTOR RELATIONSHIP

This is a team. The primary function of the team is the care of the patient within the limit set by higher authority.

The doctor is the coach of the team. He gives the orders and expects them to be carried out. He is responsible to the chief of his service for the care and treatment of his patients, the efficient operation of the ward, and the coordination of ward activities with other departments of the hospital.

The nurse is the quarterback of the team. She determines how the doctor's orders are to be executed. She is responsible to the doctor and senior nurse for the nursing care of her patients, the management of the ward, and the supervision and instruction of the corpsmen.

The corpsman is the half-back of the team. He carries out the orders of the doctor in the manner designated by the nurse. He is responsible to the doctor and the nurse for the efficient care of his patients and for carrying out his assigned duties.

As on any team, there must be mutual respect, cooperation, coordination, and loyalty among its members. Each must appreciate and understand the other's role. When each member knows where he fits, what he is to do, to whom he is responsible, and how he is to do his part, all members take personal responsibility for the team's product which is providing for the best possible care to, and for, the patient.

CORPSMAN-PATIENT RELATIONSHIP

The corpsman is in close contact with the patient throughout his stay in the hospital or sick bay. The patient frequently first makes known his wants, worries, fears, and pains to the corpsman. The tact, kindness, consideration, and understanding the corpsman shows toward the patient and his problems will help build the patient's confidence in the ability of all sick bay and hospital personnel to return him to health and duty in the shortest possible time.

The attitude of the corpsman toward his patients should be: friendly, sympathetic, kind, considerate, courteous, assuring, fair and honest to all; always interested, calm, dignified, soft-spoken and self-controlled.

The following are suggested as items the corpsman should think about, know and practice in relation to the patient or patients each day.

1. Be an example of good health. Be clean, look clean, feel clean. Use good posture and body mechanics in performing activities for your patient, for you may teach your patient good health habits while he is ill, which, if practiced, will help him keep well after he leaves your care.

2. Get to know your patient: How does he feel about his illness? His treatment? Other patients? Ward personnel? Try to find out and understand what makes him behave the way he does.

3. Be alert and observant. Learn to recognize signs and symptoms; be alert to changes in the mental and physical condition of your patient. Use your eyes, ears, nose, and hands. Read and understand the doctor's orders; if in doubt, consult the doctor or nurse.

4. Be adaptable. Learn to adjust nursing care to fit the individual needs of the patient.

5. Be skillful. Learn the routines of procedures so that they may be done with the least discomfort to your patient.

10285

6. Have regular study habits; prepare yourself to better understand the reasons for doing the job.

7. Have a plan. Use your head to save your feet. Think out what you want to do, how much time you have to do it, and the method or sequence of doing it. Examine your plan. Is it the best way to save time, materials, and produce the desired results? Will your plan make it possible for you to do the job you are capable of doing?

8. Explain your plans to your patient. Tell him what you are going to do for him and how he may help to get the best results from the procedures.

9. Protect your patient and yourself by preventing the spread of infection.

10. Teach your patient the importance of:
    a. Personal cleanliness, particularly washing his hands.
    b. Covering his mouth and nose when he coughs or sneezes.
    c. Using only his own toilet articles.
    d. Getting the proper rest.
    e. Eating the proper diet.

11. Grow in your job. Analyze your work each day — strive to do a better job the next day.

BASIC NURSING CARE

Basic nursing care, as considered in this book, consists of those environmental, hygienic, and supportive measures required by the patient for the restoration and promotion of his health and his protection against contacting any additional infection, disease, or abnormal condition.

The amount of care needed by the patient will vary with each individual. Some patients will need complete care by the nursing personnel, some will need assistance with their own care, while others will require only supervision and direction by the nursing personnel.

Patients in our hospitals are usually segregated according to clinical services. This segregation serves to protect the patient from exposure to new diseases, to provide a more specialized program of therapy for the patient, and to facilitate nursing care.

Environmental Measures

The following practices, common in the care of all patients, serve to protect the patient and prevent the spread of infection:

1. Beds are spaced at 8-foot center intervals.

2. All furniture is damp-dusted; floors are damp-swabbed.

3. Each patient is provided with a complete bedside unit:
    a. bed
    b. bedside locker
    c. chair

His necessary belongings are kept within this unit.

4. Each bed patient is provided with individual equipment such as:
    a. wash basin
    b. curved basin
    c. bedpan
    d. urinal

5. Only clean articles and utensils are brought to the patient and are disinfected or sterilized after he uses them.

6. All dishes are sterilized or sanitized after each meal.

7. All body discharges and excreta are considered as disease carriers and are treated as such.

8. Sterile supplies and equipment are used for treatments such as irrigations, instillations, surgical dressing and injections.

9. Emphasis is placed on washing hands after the care of each patient and after each task, using plenty of soap (to emulsify the dirt), friction (to loosen the dirt), and running water (to get rid on the dirt).

These practices form the basis for medical and surgical aseptic techniques which are additional measures used in caring for a patient with a communicable disease or a patient with a wound.

MEDICAL ASEPTIC TECHNIQUE is used to confine the communicable disease organisms to the patient and to protect the worker and other patients from the infection. The technique consists of isolating the patient in a separate ward, room or unit; concurrently disinfecting of materials and utensils coming from the patient; and sometimes the using of protective clothing by the worker while caring for the patient. This technique is often termed isolation or precaution technique.

SURGICAL ASEPTIC TECHNIQUE is used to protect the patient's wound from infection that may be carried in the air, by the worker, by worker's equipment, or by other patients. This technique consists of segregating the patient in a separate room or unit; sterilizing

10286

all articles that come in contact with the patient's wound or lesion and sometimes the wearing of sterilized clothing by the worker (as in the operating room).

Surgical aseptic technique includes the preparation, sterilization and handling of sterile supplies and equipment. When used in this sense, it is often termed sterile technique.

Appearance of the Ward

The ward is a unit of a hospital composed of a number of beds and other equipment necessary to provide service to and for the patients assigned to it. The ward may accommodate from 6 to 60 patients at one time and should provide a pleasant cheerful environment for patients and staff. The ward should be orderly—a place for everything and everything in its place.

The patient's unit should be a clean, comfortable place for the patient to live. While he is under your care, he will spend the greater part of his time in his unit. He will need a comfortable bed, a bedside locker for his personal gear, and a chair for himself or his visitors.

Beds should be in a straight line, away from walls with casters turned in, made up as for standard beds (see Bed Making) and spaced at 8-foot center intervals.

Bedside lockers should be on the right side of beds even with head of beds and clear of all unnecessary articles.

Bedside chairs should be in a straight line near foot of beds on the same side as lockers.

Overbed tables, when used, should be at the foot of the bed.

Window shades should be at uniform height and sills cleared of all articles.

Decks should be clear; shoes and slippers should be inside bedside lockers.

Waste baskets should be kept empty; other furniture arranged in orderly fashion.

Hygiene of the Ward

Ventilation: Provide for free circulation of air; protect patients from drafts by use of ventilators or screens.

Temperature: Maintain constant and proper temperatures during day, 68° (72° -75° during bath time), 65° at night.

Lighting: Avoid glaring lights in patient's eyes; promptly replace burned-out bulbs.

Odors: Eliminate disagreeable odors by prompt disposal of excreta, dressings, trash. Use deodorants, if necessary.

Noise: Avoid dropping and banging equipment and loud talking and laughing; wear rubber heels on shoes.

CLEANING A PATIENT'S BEDSIDE UNIT

Purpose

To insure a clean, sanitary bed and furnishings for the patient. It should be done weekly and when patient is discharged. Whenever presence of vermin is suspected, the entire unit should be cleaned.

Equipment

Basin of warm soapy water
Soap or detergent
Cleaning cloths
Hamper for soiled linen

Stripping the Bed

1. Bring linen hamper to unit.
2. Push bedside locker to back of bed; place chair at foot of bed.
3. Remove pillows, strip, and place on chair; place linen in hamper.
4. Lift mattress with one hand; pull out linen with other hand. Loosen bedding all around bed.
5. Remove spread, sheets, mattress cover separately, and place in hamper.*
6. Remove blanket and rubber sheet and place over back of chair**.
7. Take linen hamper out of unit.
8. Remove all articles from the bedside locker. Articles to be sterilized may be boiled or sent to CSR while the unit is being cleaned.

---

*Plastic mattress covers: Do not remove from mattress for routine cleaning or upon discharge of patient. Do inspect for holes and tears. Wash in same manner as rubber sheet.

**Cotton blankets: Send to laundry with other linen. Woolen blankets: If soiled, send to laundry. Requires special laundering and should be so marked. Check station instructions for specific procedures in the care of woolen blankets.

10287

Cleaning Unit

1. Place cleaning equipment on top of locker.
2. Swing mattress clockwise to assure complete turning of the mattress.
3. Damp dust top and nearest side of mattress. Pay particular attention to tufts and crevices.
4. Raise the headrest of the Gatch bed. With damp cloth, wash springs, coils, bed frame; follow with dry cloth.
5. Lower headrest. Turn mattress clean side down onto the upper half of the bed. Damp dust mattress.
6. Place rubber sheet on springs, wash with damp cloth and dry. Turn onto mattress clean side down and wash other side.
7. Place pillows on springs, dust with damp cloth and turn onto mattress clean side down; do other side. Place blanket over head of bed.
8. Wash lower springs, coils, bed frame as before. With a damp cloth, wash chair; dry well.
9. Wash locker inside and outside; dry well.
10. Use detergent, if necessary, for enamel surfaces.
11. Take equipment to utility room. Scour cleaning basin, place in sterlizer, boil 20 minutes; wash out cleaning cloths, and hang up to dry.
12. Swab deck.
13. Remake bed; straighten unit.
14. Whenever possible, allow unit to air 6 to 24 hours before remaking bed.

BED AND BUNK MAKING

The hospital bed is higher than the bed in the barracks. The purpose is to bring it up to a better working level and thus reduce fatigue and avoid backstrain for the personnel caring for the patient.

Figure 10-1.—Cleaning a bedside unit.

10288

The bed with a Gatch frame is the fundamental device for making the patient comfortable. The crank-operated Gatch frame permits raising and lowering of the head and foot; the newer frames may be adjusted to many different positions and have attachments to support fluid containers, orthopedic apparatus, and sidebars. The legs of the bed have rubber tired wheels to make them movable and are equipped with brakes to make them stationary. The mattress in most naval hospitals is of the inner spring type and should be firm, even, and clean. The bedding under the patient should be smooth and tight. The upper bedding should be loose, of light weight, draped evenly and of sufficient warmth and length to keep the patient comfortably warm.

A HI-LO bed has the Gatch frame plus a lever for raising or lowering the height of the bed. These are usually used for elderly patients.

The bunk aboard ship is narrower than the hospital bed and may not have a Gatch frame. The head or foot of the bunk may be raised by inserting a board under the mattress. (See fig. 10-2A.)

OCCUPIED BED

Purpose:

To change bottom sheet and draw sheet, with least exertion to patient.

Equipment:

Linen as needed.
Hamper for soiled linen.

Procedure:

1. Place chair at foot of bed; push bedside locker back of bed.
2. Loosen all bedding at sides and foot of bed.
3. Remove pillow, strip case, and place on chair.
4. Remove spread in quarters, fold from top to bottom, pick up in center, and place on back of chair.
5. Remove blanket in same manner.
6. Turn patient to one side of bed.

To change bottom sheet, draw sheet:

1. Roll draw sheet close to patient's back (Fig. 10-4).
2. Fold rubber sheet up over patient.
3. Roll bottom sheet close to patient's back.
4. Place clean sheet on bed, center fold in center of bed, narrow hem even with foot of mattress.
5. Tuck in excess at head of bed, miter corner, and tuck in at side.
6. Bring down rubber sheet; straighten.
7. Fold large sheet in half, hem to hem, smooth side out.
8. Place on bed, fold toward head of bed, over-lapping rubber sheet.
9. Tuck in rubber and draw sheets together.
10. Roll patient over to completed side of bed toward you.
11. Remove wrinkles from under patient.
12. Go to other side, fold in soiled sheets, remove, and place in linen hamper.
13. Turn back draw sheet and rubber sheets over patient.
14. Pull bottom sheet tight and smooth; proceed as for first side.
15. Pull rubber and draw sheets tight; tuck under mattress. Do center portion first, then upper and lower ends.
16. Bring patient to center of bed.

Top bedding:

1. Place top sheet over patient, wide hem even with top of mattress; turn down to make 10 inch cuff.
2. Ask patient to hold clean sheet.
3. Reach under, grasp soiled sheet, remove, and place in linen hamper.
4. Place blanket 6 inches from top of mattress. Make pleat in sheet and blanket over patient's toes, tuck in excess at foot, and miter corner. (Fig. 10-5).
5. Place spread even with head of bed; fold spread over blanket at head of bed; fold sheet over spread.
6. Tuck in excess at foot, miter corner, and allow triangle to hang loosely. Top sheet and spread may be mitered together when blanket is not needed.
7. Fit pillow into corners of case; place under patient's head, seam toward back, closed end toward entrance to ward.
8. Adjust Gatch bed as ordered.
9. Straighten unit; leave bedside stand within reach of patient.

DPS: 10289

BED MAKING

(A) Mattress cover

Fold cover back on itself. Place top corner of mattress into cover, far corner first, flap of cover on top of mattress.

Pull cover down on mattress - working each side alternately.

Fold under excess at foot. Smooth out cover, tighten at sides.

(B) Bottom sheet

Place center fold of sheet in center of bed, narrow hem even with foot. Fold excess sheet under mattress at head of bed.

(C) Mitered corner— Pick up hanging sheet 12 inches from head of bed.

(1)

(2) Tuck lower corner under mattress.

(3) Hold fold with left hand. Bring triangle down over side of bed.

(4) Tuck sheet under mattress.

(D) Top sheet

Center fold in center of bed, wide hem even with top of mattress at head of bed, Tuck excess under mattress at foot.

(E) Blanket— Center, in center of bed 6 inches from top of mattress. Fold excess under mattress at foot of bed.

Make mitered corner at foot of bed. Tuck in triangle - do not tuck in sides

(F) Spread— Center fold in center of bed even with top of mattress. Tuck excess under mattress at foot. Miter corner, allow triangle to hang. Fold cuff of top sheet over spread at head of bed.

Repeat on other side of bed.
Pull sheet taut before tucking under mattress.

PILLOWS

Open pillow cover and fold it back on itself. Gather pillow lengthwise, fit corners of pillow into corners of pillow cover. Grasp pillow through pillow cover, pull cover down over remainder of pillow. Repeat for pillow case.

Figure 10-2A.—Bed making.

10290

Figure 10-2B.—Bunk making.

Modifications

1. Patient's top sheet may be used as draw sheet; change top sheet first; then fold for draw sheet. Proceed as above.

2. Spread may be too short. Make foot of bed; then fold excess, if any, over blanket.

3. For patients with long-term illnesses, remove, wash and replace rubber sheet weekly or more often as necessary.

THE BUNK ABOARD SHIP is made in the same manner as the bed, with the following exceptions:

1. The patient is turned toward the corpsman.

2. The side of bunk nearest the bulkhead is completed first, the patient is then turned toward the bulkhead and the other side of the bunk is completed.

3. The top bedding is made with envelope corners at the foot of the bunk (Fig. 10-2B).

UNOCCUPIED BED

Purposes:

To provide a clean, warm, sanitary bed or bunk to receive a patient, and to protect the mattress.

To provide a neat, uniform appearance to a ward or sick bay.

Equipment:

1 mattress cover
2 sheets
1 blanket
1 spread
1 pillow with cover and case

0C50A 10291

Figure 10-3.—To protect mattress of a bed or bunk.

When additional protection of the mattress is desired, add

1 rubber draw sheet
1 cotton draw sheet

Procedure:

Follow steps in figures 10-2A and 10-3. When a blanket is not needed, the top sheet and bedspread may be mitered together at the foot of the bed.

STORAGE OF PERSONAL EFFECTS

Purpose

To safeguard patient's gear; to safeguard personnel handling patient's gear; to simplify procedure for care of patient's clothes.

Procedure During Hospital Stay

In Ward

1. Check hospital instructions on care of patient's gear on the ward.
2. Toilet articles or kit may be kept in bedside locker.
3. Uniform may be placed in the ward clothes locker, which must be kept locked except when one of the ward personnel is present. All items in this locker must be properly tagged. A schedule of hours when locker is open for deposit and withdrawal by patients should be posted on ward bulletin board.

HOSPITAL BAG ROOM—for storage of all personal effects not needed on ward.

1. Hours for deposit and withdrawal are scheduled by the bag room.
2. Check local instructions before sending patient to this room.
3. Ambulatory patient will break seal and deposit or withdraw the desired items in the presence of the bag room attendant.
4. The bag room attendant will make a note of the deposit or withdrawal on the Baggage Record Card.
5. The patient will sign note.
6. The bag room attendant will draw a line through the broken seal numbers on the record card, top and stub of Patient's Effects Tag; attach new seals to the gear, and enter new seal numbers on the record card and Patient's Effects Tag; give the patient a copy of the new seal number(s).
7. Bed patient will list items he wishes withdrawn or deposited in the bag room.
8. The ward medical or nurse officer will sign a memorandum designating a corpsman to handle the transaction.
9. The bag room attendant will follow the procedure as set out under Ambulatory Patient in resealing the gear.
10. The memorandum will be attached to the Baggage Record Card.

10292

Figure 10-4.—Changing the bottom sheet.

On Discharge from Hospital

1. Patient will report to bag room on day of discharge with check-out slip.
2. Bag room attendant will sign check-out slip and will staple Patient's Effects Tag to Baggage Record Card.
3. Bag room attendant will forward cards to record office for inclusion in patient's chart.

CARE OF VALUABLES

Purpose

All property is valuable to its owner and precautions must be taken to safeguard the belongings of a patient.

Procedure

1. All patients must be informed of the wisdom of depositing their valuables with the disbursing officer for safekeeping.

2. Patient must be made to understand that no responsibility is assumed by the hospital if he retains his valuables at his bedside. A signed statement by the patient should be included in his chart if he insists.

3. Temporary storage of valuables in the narcotic locker or the ward medicine locker is prohibited.

4. Valuables are deposited for safekeeping with the disbursing officer during the day and with the officer of the day after regular working hours.

5. Ambulatory patient will be sent to the disbursing officer or officer of the day. Patient and officer will inventory valuables. The officer will give the patient a signed receipt.

6. Bed patient will inventory his valuables with the ward medical or nurse officer. The

10293

Figure 13-4.—Single automatic positioning system schematic diagram.

the input drawn by the ARC-27. When receiving, the supply power is 225 volt-amperes, a reduction of 40 percent.

The basic set is a-c supplied and hence does not employ a dynamotor. An alternate a-c/d-c version contains a dynamotor which operates only during the transmit mode, thereby minimizing brush wear and other sources of malfunctions common to rotating power equipment.

PRESSURIZATION

The pressurized case of the receiver-transmitter (fig. 13-1) serves as a rugged protective cover, an effective radiation shield, and an efficient heat exchanger. The case, which slides over the main chassis to make airtight contact with the front casting, is double walled and is constructed of corrugated aluminum. A rubber ring mounted between the case and the front casing insures the airtight seal.

Purpose and Method

The need for pressurizing the ARC-52 is to insure a constant dielectric strength of air within the equipment at all altitudes. This tends to reduce equipment failures at higher altitudes; these failures are normally caused by arcing in the less dense atmosphere. A more detailed discussion on pressurization (as it relates to the atmospheric environment) is found in chapter 6. Pressurizing is normally accomplished by the use of the MK-20A/UP dehydrator hand pump to pressurize the unit with 3 to 5 psi (gage) of dehumidified air.

COOLING

Cooling air is forced into what is called the plenum chamber between the walls by an external blower on the transceiver's front panel. After absorbing heat from the inner wall of the case, the air is exhausted through vents in the

1027 1028

Figure 10-5.—Toe pleat.

officer will give the patient a temporary receipt and take the valuables to the disbursing officer. The patient will be given the disbursing officer's receipt and the temporary one will be destroyed.

7. Incompetent patient is unable to participate in the inventory of valuables. The ward medical and nurse officer will inventory and deposit his valuables with the disbursing officer. The receipt will be placed in the patient's case jacket in the record office.

10294

CHAPTER 11

CLINICAL RECORDING AND COLLECTION OF SPECIMENS

THE PATIENT'S CHART

PURPOSE

To provide a clear and concise record of the patient's condition and progress throughout each 24-hour period; to record effects and results of treatment the patient is receiving; to aid the doctor in making a diagnosis and in prescribing treatment; to help the corpsman adjust his nursing care to fit the needs of the patient; and to provide records for study, research, and statistics. Such written records are termed clinical records. They are maintained for all patients.

Arrangement of Patient's Chart

The patient's chart is composed of a series of standard clinical record forms. Each form is assigned a number in the series ranging from Standard Form 501 to Standard Form 539 and has been designed for a specific purpose. All forms will not be required for all patients; but each patient should have the following basic clinical chart arranged in NUMERICAL and CHRONOLOGICAL order:

SF 501 – Diagnostic Summary
SF 502 – Narrative Summary
SF 504 – History, Part I
SF 505 – History, Part II and III
SF 506 – Physical Examination
SF 508 – Doctor's Orders
SF 509 – Doctor's Progress Notes
SF 510 – Nursing Notes
SF 511 – Temperature - Pulse - Respiration
SF 514 – Laboratory Report (Reports 514A through Q are stapled to this sheet)
SF 519 – Radiographic Report (Reports 519A are stapled to this sheet)

When other forms in this series are used, they should be inserted into the chart in numerical order. All clinical records pertaining to each patient should be kept together in one chart holder.

The corpsman is responsible for maintaining the temperature, pulse, and respiration sheets, nursing notes, intake and output records and for plotting charts when used. He is also responsible for stapling or inserting other forms or reports in the chart.

Each sheet of the patient's chart should be neat and pleasing to the eye. When writing an entry, try to use lettering that is uniform in height and spacing. Leave a one letter space between words.

Each sheet of the chart should have complete identifying data at the foot of the page. These data should be legible, correct and complete: Patient's last name, first and middle name, service number, case number, date of admission, rank or rate, branch of service, ward, hospital or medical facility. These data may be typed, lettered or mechanically imprinted.

The MECHANICAL IMPRINTER is used for patient's identifying data on the clinical records. When used properly and maintained in good working order, the imprinter will save time and assure legible data (fig. 11-1).

An IMPRINTER PLATE for each patient is made by the admission unit and sent to ward with the patient.

The Mechanical Imprinter

1. Insert patient's plate, face up under the clips, into the bed of the machine.
2. Position the patient's record face down over the plate.

10295

HAND IMPRINTER

Ward Plate Inserted
in Hand Imprinter

Sample Impression

Figure 11-1.—Mechanical imprinter and sample impression.

3. With the left hand holding the record, lower the head of the machine with the right hand and push the lever downward to the limit of its stroke.

4. Raise the head of the machine and remove the imprinted record. Check the record for complete and legible imprinting.

5. Remove the patient's plate and place it in the appropriate place in the ward file.

Care of the Imprinter

1. If a dater is included in the ward imprinter, it must be set daily, using a wooden stylus, never a metal object.

10296

2. The face of the patient's plate should always be clean and even. (When adhesive tape is used to identify a patient's plate, it should always be placed on the back of the plate).

3. If the imprinted record is not legible, check the following:

a. Ribbon — Is it dry, torn, or when was it last replaced?

b. Plate in the bed of the machine may be off balance.

c. Roller in the head of the machine may be worn and need replacement.

d. Patient's plate may have been cut unevenly.

4. If the ribbon, machine, plate, or roller is defective, return machine to the proper department for repair. If patient's plate is defective, request a new plate.

NURSING NOTES (SF 510)

This form is a chronological record of the patient's condition and progress during his hospital stay. The recording of the patient's condition and progress is the responsibility of the nursing personnel on the ward.

The primary requisites of clinical records are accuracy and completeness. The recordings must be in language which is understood by all who have access to the chart. When abbreviations or symbols are necessary, use only those listed at the end of this chapter.

The entries must be factual and truthful without interpretation. If interpretation of a patient's subjective symptom is necessary, qualify the statement by "appears" or "seems". Wherever possible, record patient's complaints in his exact words. Each entry need not be a complete sentence but should contain sufficient words to convey a complete thought.

1. All entries should be written or printed in black or blue black ink. Black or blue-black, ballpoint pens may be used. (Entire 24-hour period) (fig. 11-2A).

2. Navy date and time shall be used. (1 Nov 1965, 0220);

a. Date, shall appear at midnight, at the beginning of each new page, on admission and discharge.

b. Hour shall accompany each new entry.

3. Entries shall be signed with the full signature of the person making them. The signature may be placed at the end of the day's entries if the same person has made all of them. EXCEPTION: Narcotics, prn. stat and one time medications and treatments must be charted as soon as given or completed and the signature of the person carrying out the order must follow each entry.

4. When an error is made, draw a straight line through the error. Write "Error" above the line. If for any reason, a page must be copied, it must be marked "Copy" and the original is marked "Copied" and retained in the back of the chart (fig. 11-2B). In either case, the signature of the person making the corrections is required.

5. Include complete patient identification data in the spaces provided.

6. Entries for liquid measures are recorded in the metric system.

Include in the Admission Notes

1. Date, time and manner of admission.

2. Chief complaint and other complaints of the patient.

3. Your observations of the patient and any pertinent information received from relatives or others accompanying the patient.

4. Abnormal characteristics of the pulse and respiration must be fully described. (Record TPR only on SF 511).

5. Notification of the doctor.

6. Medication and nursing measures given.

Nursing Notes During Hospital Stay

1. All observations made. Objective and subjective symptoms. The effects of treatments and medications. Changes in the patient's physical condition or behavior.

2. All supportive nursing care given, such as hygienic, comfort and diversional measures. Indicate the degree to which the patient participates in his care.

3. Use of restraints, siderails, and reasons why applied.

4. Notification of doctor.

5. Doctor's visit other than routine sick call.

6. Treatments and consultations received in other departments, clinics.

7. Working order of apparatus in use, such as tidal drainage.

8. Specimens sent to laboratory.

9. Any accident or unusual happening. Record time and how the event occurred, the effect on the patient, whether the doctor was notified and the time he examined the patient, and the

Standard Form 510
510-106

Figure 11-2B.—Sample nursing notes (SF 510).

10299

completion and submission of a special report if one is required at your station.

10. Serious or critical lists. Record the time the patient is placed on the S. L. or C. L., whether next of kin are present at the bedside, and the completion and forwarding of the S.L. or C. L. to the proper departments as required by your station. Follow the same procedure when the patient is removed from the S. L. or C. L.

11. Administration of religious rites. Record the time and by whom the rites were administered.

12. Diets. Record the type of diet. Record patient's likes and dislikes of foods and the amount of food he eats if such is significant in his care.

13. Nourishment. Record the type of nourishment when significant in the care of the patient.

14. Single order for medication or treatment:

a. Medication. Record time in hour column, record name of drug, dosage and manner of administration if other than by mouth, after it has been given, followed by signature, in "observations" column.

b. Treatment. Record time in hour column, record name of treatment, amount of solution if used, and duration of treatment if for prescribed time, after it has been given, in "observations" column.

15. Repeated or running orders for diets, medications or treatments are charted in the "observations" column followed by the hours to be repeated. When given make a diagonal line through the hour and place initials above. When a diet, medication or treatment is not given for any reason, record the hour, circle and initial it, and record the reason for the omission in the body of the Nursing Notes at the appropriate hour. When a diet, medication or treatment is discontinued, enter DC and initial above the entry.

TEMPERATURE-PULSE-RESPIRATION, FAHRENHEIT (SF 511)

1. Form SF 511 is usable for one week. The graph is divided into seven major columns—one for each day. Each daily column is subdivided into two parts — a.m. and p.m. Each subdivision is further divided by two vertical dotted lines. Note that the dots in the lines divide the vertical spaces into five even divisions, (for each two-tenths degree of temperature or two pulse beats).

2. Use black or blue-black ink for all entries. Fill in heading at top of page. The day of admission is the first hospital day. The day of operation or delivery is lettered "Operation" or "Delivery"; the following day is the first postoperative or postdelivery day. Record the hours TPR's are taken.

3. After patient's name at the bottom of page print his serial number, rank or rate, branch of service, or civilian status, or use the mechanical imprinter if available.

4. For every four hour and twice-a-day temperature and pulse readings, place the recording within the dotted lines (fig 11-3).

5. For four-times-a-day readings, place the recordings on the dotted lines.

6. Use the same symbol, a dot the size of pinhead, for temperature and pulse. Record by date corresponding vertically to hour, horizontally to scale. Connect the dot with previous recording by a solid line.

7. Record number of respirations in space corresponding vertically to hour.

8. When blood pressure is ordered more than two times a day and pulse and respiration more than six times a day, they may be recorded on the Plotting Graph, (SF-512).

9. Record height and weight on admission. Record subsequent weight in correct date columns.

10. The blank space below the graph may be used as desired; for example: intake and output 24 hour totals, blood transfusions, totals of specific drugs.

PLOTTING CHART (SF-512)

This form may be used for additional graphic representation of data as required.

USE:

Blood pressure recording
Weight chart
Drainage chart
Pulse, respiration, and blood pressure

General Rules for Constructing Graphs

1. Purpose of graph must be known; print purpose of graph on upper left-hand space provided (fig. 11-4).

2. A graph should always read from left to right.

10300

Figure 11-3.—Sample temperature-pulse-respiration (SF 511).

3. Measurement should be calibrated along vertical portion of graph.
   a. Scale should be at a definite and uniform rate of progression. EXAMPLE: 0—10—20—30.
   b. Scale should be labeled at top to show units of measure. EXAMPLE: cc—lbs—mm—gm.

4. Passage of time should be noted along horizontal portion of graph. EXAMPLE: Dates and hours measurements are made.

5. Meaning of symbols used in graphs should be shown in a key to the side of the graph.

6. When lines are used in graphing, they should be labeled to the left of their starting points.

INTAKE AND OUTPUT WORKSHEET (DD 792)

Whenever a record of intake and output of fluids by the patient is required, the Nursing service — Twenty-four Hour Patient Intake and

10300
10301

Figure 11-4.—Sample plotting chart (SF512).

Output Worksheet (DD 792) should be used. The worksheet is self-explanatory (fig. 11-5).

At 2400 hours daily, the intake and output totals should be recorded in the Nursing Notes (SF 510) or TPR Sheet (SF 511) of the patient's chart.

When DD 792 is not available:

1. Rule a sheet of paper into columns for time, intake, and output.

2. Each time a patient drinks, is fed through a gastric tube, or receives fluids by intravenous or hypodermoclysis, record time and the amount of intake, using the metric system. The following equivalents may be used:

Medicine glass	30 cc
Small fruit cup	120 cc
Coffee cup	120 cc
Large coffee mug	180 cc
Half pint milk	240 cc
Large soup bowl	240 cc
Large water glass	240 cc

DD FORM 1 SEP 54 792

U. S. GOVERNMENT PRINTING OFFICE: 1955 O— 329456

Figure 11-5.—Sample Intake and Output Worksheet (DD 792).

Each time a patient voids, or loses fluids by vomiting, gastric or urinary drainage or diarrhea, record time and the amount of output.

4. Total intake and output columns at 2400 and record in the Nursing Notes (SF 510) or TPR Sheet (SF 511) of the patient's chart. Start a new sheet at 0001.

S0C0110303

Figure 13-5. —Mechanical drive subassembly of tuning system.

top of the cover. Inside the air-sealed container an axial-flow blower circulates the air to improve the heat transfer.

All blowers are a-c operated so that brush wear and commutator faults are eliminated.

The case is designed structurally to withstand atmospheric internal pressure with complete absence of external pressure. Extra ruggedness in the shock mounts helps to overcome the effects of the high stresses occurring in catapult takeoffs and arrested landings on aircraft carriers.

THEORY OF OPERATION

The ARC-52 system is shown in block diagram form in figure 13-6. A relay switches the signal and it goes through the amplifier in the same direction both in transmit and receive.

The system employs double-conversion superheterodyne operation to provide maximum selectivity and sensitivity. In reception, the incoming signals are heterodyned successively in two mixer stages with injection frequencies from two separate sources to produce the desired intermediate frequencies. Conversely, during transmission a basic frequency is mixed with the two injection frequencies to provide a carrier in the required frequency range.

Injection signals in the 200- to 370-mc range are derived from the spectrum generator (fig. 13-6) in which the fundamental signals are produced by a crystal oscillator, then fed through a frequency multiplication system, and amplified.

Injection frequencies in the 21.85- to 31.75-mc range are produced by heterodyning the output of a crystal oscillator having a 24.9- to 33.9-mc range with the output of a crystal oscillator with a 3.05- to 2.15-mc range.

In reception, the incoming signal is fed through an RF amplifier to the first mixer, where it is heterodyned with the 200- to 370-mc output of the spectrum generator and amplifier. The result is a 20.0- to 29.9-mc first IF signal, which is amplified and fed to

DIAGNOSTIC TESTS AND EXAMINATIONS

The collection of specimens from patients for examination is a very important detail. The doctor must sign the request for the test or examination. Collecting is usually done by the hospital corpsman and the performance depends upon his conscientiousness, sense of responsibility, and understanding of what is required.

The object of collecting specimens is to provide an accurate sample of body fluid or tissues for examination. The examination results provide the physician with information to assist him in diagnosis, to help determine the progress of the patient's disease, and to furnish information regarding results of the treatment employed. Specimens are examined by general appearance, and by chemical and microscopic methods.

Diagnostic and therapeutic procedures have so greatly increased in number, scope, and complexity that the corpsman may find himself spending the greater portion of his time on duty assisting with or performing these procedures.

In order to intelligently assist with or perform these procedures the corpsman should know:

1. How and why the procedure is done.
2. What care the patient should have before, during and after the procedure.
3. What role he takes in the procedure; what part the doctor or technician assumes.
4. What equipment is necessary for the procedure; whether the equipment should be clean or sterile.
5. The time of the day the procedure may be performed to obtain the best results.
6. What symptoms and reactions are expected as a result of the procedure. What symptoms or signs of untoward reactions may occur.

When assisting with or performing these procedures, always strive to keep in mind that each one has been ordered by the doctor for the patient. The benefit the patient will derive from the procedure will depend to a considerable degree upon your ability to explain the procedure sufficiently to him so that he understands what is to be done, why the procedure has been ordered, and how he may help to assure the success of the procedure.

Preparation of the Patient

Explain the test or examination to the patient.

Show the patient how to cooperate to make a successful test or examination.

Provide transportation (wheel chair, stretcher) when test or examination is performed in another ward or department.

Care of the Patient after Test

Relieve pain if present.

Heat and serve food if meal has been withheld.

Give bath or a.m. care if either have been omitted.

Charting — Nursing Notes

1. Specimens:
   Time of collection
   Type of specimen
   Name of test ordered
   Amount of specimen in ml. if measurable.
   Any other item affecting the result of the test.
   EXAMPLE: 1000: Bromsulphalein 25 mg. I.V. given by Dr. Jones.
   1030 Blood specimen collected.

2. Special tests or examinations:
   Time of the test.
   Name of the test.
   Department performing the test.
   Name of the doctor doing the test if done on the ward.
   Amount and description of fluid obtained if applicable.
   Special preparation of the patient for the test.
   Reaction of the patient to the test.
   EXAMPLE: 1000: Lumbar puncture by Dr. Jones. 5cc. clear, colorless spinal fluid obtained. Manometer pressure 150mm. Patient placed in prone position. Patient cautioned to remain flat in bed.
   1030: Patient complains of headache.

10304

COLLECTION OF SPECIMENS

Observe the nine "rights" for collecting specimens

Be sure that –

1. The right specimen, from
2. The right patient, collected in
3. The right manner, at
4. The right time, into
5. The right container, in
6. The right amount, and with
7. The right label, is taken to
8. The right place in the laboratory, and handed to
9. The right person.

Caution

When collecting specimens:

1. Wash your hands before and after touching specimens and containers.
2. Never use a cracked receptacle.
3. Allow no opportunity for the patient to deceive, as one wishing to seem more or less ill than he really is might get another patient to void, expectorate, or produce some other specimen for use.
4. Never leave specimens in the ward, nor uncovered in the head or lavatory; but when necessary, while further collection is being made, keep properly covered in an isolated place in the heads or lavatory.
5. Keep the outside of the container clean to protect other personnel handling the specimen.
6. Attach request for examination to the specimen container with a rubber band, string or clip. Exception: Keep request separate when specimen is from a patient with a communicable disease. Place specimen container inside a clean paper bag and clip request to clean side or bag.
7. Do not send specimens to the laboratory that have been spoiled by cigarette butts, matches, tissues or other debris.

URINALYSIS – ROUTINE AND MICROSCOPIC

Clean Specimen

Equipment

Urinal or bedpan
Specimen bottle with cap
Rubber band
Standard Form 514A

Procedure

1. Patient voids into clean urinal or bedpan. The first morning specimen is preferred.
2. 120 to 150 cc is poured into specimen bottle.
3. SF 514 A is wrapped around bottle and held in place by a rubber band.

Duty of Ward Corpsman

1. Make out request.
2. Collect specimen, and send to laboratory.
3. When report is received, staple the SF 514A to the SF514 in patient chart (fig. 11-6).

Sterile Specimen

Equipment

Catheterization tray
Sterile specimen bottle
Sterile 4 x 4 (2)
Rubber bands (2)
Standard Form 514A

Procedure

1. Patient must be catheterized; however if physician so orders, the specimen may be collected in the following manner:
   a. Meatus throughly cleansed with soap and sterile water using cotton balls.
   b. Patient voids directly into a sterile specimen bottle after voiding and discarding the first ounce of urine.
   c. Specimen is covered with sterile 4x4s.

Duty of Ward Corpsman:

Same as for clean specimen.

24 Hour Specimen (Quantitative)

Equipment

Urinal or bedpan
Gallon bottle (from laboratory)
Shipping Tag
Standard Form 514A

10305
10304

Preparation of SF 514 A-M.
Complete identifying data.

Complete additional information required by test or examination.

Insertion in Clinical Chart.
Call attention of medical officer to report.

Staple report (left side only) to SF 514.

Indicate test or examination performed across foot of report.

Staple each subsequent report on top and above the previous report so that date and action performed are visible. Indicate date of report when it is not visible in lower section of the form.

REGISTER NO.

WARD NO. 9

LABORATORY REPORTS
Standard Form 514

U. S. GOVERNMENT PRINTING OFFICE 10—50800-6

Figure 11-6.—Sample laboratory reports (SF 514).

Procedure

1. Shipping tag is made out with patient's name, rate, date, and type of specimen; tied to gallon bottle.
2. All urine voided is placed in gallon bottle.

Duty of Ward Corpsman

1. Instruct the patient in regard to the required procedure.
2. Collect specimen for 24 hours (0700 to 0700), discarding the first morning specimen.
3. Continue as for clean specimen.

Clinitest. Reagent Test for Sugar

Equipment

Clinitest reagent tablets No. 2102.
Bedpan or urinal
Medicine dropper
Clinitest color chart

Procedure

1. Collect as for single specimen 20-30 minutes before meals or as ordered by doctor.

19300L

2. Place 5 drops of urine in test tube. Rinse dropper then add water to test tube. Drop 1 clinitest tablet into tube, watch solution boil. Wait 15 seconds after boiling stops, then shake tube gently.
3. Hold tube next to color chart and compare.
4. All shades of blue negative.
5. More than 2 percent causes rapid change to green, olive tan, orange, brown: Positive.

Duty of ward corpsman

1. Collect urine specimen and conduct test.
2. Record results on patient's chart; report positive results to ward nurse or medical officer.

FECES

Ova and Parasites (O & P)

Equipment

Clean bedpan
Screw-cap bottle
two tongue blades
Standard Form 514G

Procedure

1. Collect specimen in clean bedpan.
2. Take bedpan to utility room
3. With tongue blades, remove feces (at least the size of a walnut) from pan and place in the bottle.
4. Screw cap on tightly.

Duty of Ward Corpsman

1. Collect specimen
2. Send specimen to laboratory immediately.
3. When report is received, staple the SF 514G to the SF 514 in patient chart.

Occult Blood

Equipment

Same as O & P.

Procedure

1. Same as O & P except add that the patient is placed on a meat-free diet at least 2 days before specimen is collected.

Duty of Ward Corpsman

1. Instruct patient regarding the need for a meat-free diet for 2 days before specimen is collected.

Amoeba

Equipment

Same as for O & P plus "basin of warm water."

Procedure

Collect specimen in the same manner as for O & P.
Place bottle containing specimen in basin of warm water and take to laboratory.

Duty of Ward Corpsman

Same as O & P except add "send immediately to laboratory in warm water bath, so that movements of amoeba may be seen."

SPUTUM

Single Specimen

Equipment

Wide mouth screw-cap bottle or jar (60 cc)
Standard Form 514K

Procedure

1. Before breakfast patient rinses mouth, coughs deeply, and expectorates directly into sputum bottle or jar.
2. Specimen must be sputum, not saliva.

Duty of Ward Corpsman

1. Instruct the patient.
2. Collect and send specimen to laboratory.
3. When report is received, staple the SF 514K to the SF 514 in patient chart.

GASTRIC CONTENTS

Gastric Wash (Examined for tuberculosis organisms

10867

Equipment

Levin tube in basin of cracked ice or cold water
Lubricant, water soluble
Rubber sheet and cover
Curved basin
Sterile: syringe 20 cc, specimen tube, normal saline solution
Standard Form 514K

Procedure

1. Specimens are collected before breakfast.
2. Levin tube is passed into stomach through the nose.
3. Test to ascertain that tube is in stomach and not in respiratory tract;
   a. Insert end of tube in water; if bubbles appear withdraw the tube.
   b. Listen to end of tube for breath sounds; if audible withdraw the tube.
4. Observe patient's breathing and voice, to tell whether tube is passing correctly or not.
5. Syringe is attached to the Levin tube.
6. Specimen is withdrawn and placed in specimen tube.
7. If fluid cannot be aspirated: 15 cc of saline solution is injected through tube, specimen withdrawn and placed in specimen tube.

Duty of Ward Corpsman

1. Explain procedure to the patient.
2. Place patient in sitting position.
3. Place covered rubber sheet over chest.
4. The introduction of tubes through the nose or mouth into the stomach is usually the responsibility of the doctor. However, there are times when a corpsman may be called upon to insert a tube or teach his patient how to do so.
5. Send specimen with request to laboratory immediately.
6. When report is received, staple the SF-514K to the SF-514 in patient's chart.

Gastric Analysis (Examined for Hydrochloric acid)

Equipment

Levin tube in basin of cracked ice or cold water (curved basin)
Lubricant (may be water, saline, mineral oil, or lubricating jelly)
Clean test tube
Rubber sheet and cover
Standard Form 514 F

Procedure

Same as for gastric wash except for omitting introducing of saline.

Duty of Ward Corpsman

Same as for gastric wash.

BLOOD

1. Blood examinations are requested on Standard Forms 514B, C, D, K and N. These specimens are collected by the laboratory technicians.
2. Blood is examined for cell counts, coagulation and bleeding times, hematocrit reading, sedimentation rate, serological tests, various chemistries, and other examinations.
3. Specimen for blood chemistry must be collected when the patient is fasting; that is, before breakfast.

BODY FLUIDS

Fluids from body cavities are withdrawn by means of aspiration performed by a doctor. This is strictly an aseptic or sterile procedure. The duty of the ward corpsman is to:

1. Order the equipment from Central Dressing or Central Supply Room.
2. Prepare the patient.
3. Assist the doctor.

Some examples of such withdrawals are:
   a. Lumbar puncture. for spinal fluid.
   b. Paracentesis . . . for abdominal fluid.
   c. Thoracentesis. . . for pleural fluid.
   d. Aspiration of fluid from a joint such as the knee.

ABREVIATIONS AND SYMBOLS

Abbreviations	Meaning
Relating to Personnel	
CO	. . . . . commanding officer
OOD	. . . . . officer of the day
WMO	. . . . . ward medical officer
Sp W	. . . . . special watch

CU601
10308

Relating to Wards and Services

CD	communicable disease
CDR or CSR	central dressing or supply room
EENT	eye, ear, nose and throat
GU	genitourinary
Lab	laboratory
Mechano	mechanotherapy
Med	medical
NP	neuropsychiatric
OB	obstetrical or maternity
OR	operating room
OT	occupational therapy
Ped	pediatric or children
Pharm	pharmacy
PT	physical therapy
SOQ	sick officers quaters
Surg	surgical
TB	tuberculosis
Wd	ward

Relating to Census

CLR	census last report
A	admitted to hospital
AOW	admitted from other ward
TOW	transferred to other ward
DD	discharged by death
D	discharged from hospital
Occ	occupied beds
Vac	vacant beds
Cap	bed capacity
Dep	dependent
VAB	Veterans Administration beneficiary
L	leave or liberty
AWOL	absent without leave
PAL	prisoner at large
CL	critical list
SL	serious list

Relating to Physical Examination

BP	blood pressure
L.L.L.	left lower lobe
L.L.Q.	left lower quadrant
L.U.L.	left upper lobe
L.U.Q.	left upper quadrant
os	mouth
O.S.	left eye
O.D.	right eye
P.E.	physical examination
R.L.L.	right lower lobe
R.L.Q.	right lower quadrant
R.M.L.	right middle lobe
R.U.L.	right upper lobe
R.U.Q.	right upper quadrant
T.P.R.	temperature, pulse, respiration

Relating to Tests and Examinations

BMR	basal metabolism rate
BSP	bromsulphalein test
BUN	blood urea nitrogen
CBC	complete blood count
EECG	electroencephalogram
ESR or Sed rate	erythrocyte sedimentation rate
GB Series	gallbladder series of X-rays
GI Series	gastrointestinal series of X-rays
Hgb	hemoglobin
IVP	intravenous pyelogram
LP	lumbar puncture
NPN	nonprotein nitrogen
PSP	phenolsulphonphthalein test
Rbc	red blood cell
sp.gr.	specific gravity
S. & A.	sugar and acetone
VPC	volume packed cells
wbc & diff	white blood cell and differential count

Relating to Medicines

Amp	ampoule or ampule
h or sc	hypodermic or subcutaneous
I.M.	intramuscular
I.V.	intravenous
p.o.	by mouth
p.r.	by rectum
I.D.	intradermal

Relating to Weights and Measures

aa.	of each
ad.lib	as much as desired
cc.	cubic centimeter
ʒ	dram
Gm	gram
gr.	grain
gtt.	drop (drops)
Kg.	kilogram or 1,000 grams
L	liter
lb.	pound

60809

m. or min ..... minim
mg ..... milligram, 1/1000th of a gram
mil. or ml ..... milliliter, 1/1000th of a liter
℥, oz ..... ounce
pt ..... pint
q.s. ..... sufficient quantity to make
qt ..... quart
SS ..... one-half
t. or tsp ..... teaspoon
T. or tbsp ..... tablespoon

Relating to Time

a.c. ..... before meals
b.i.d. ..... twice a day
h.s. ..... hours of sleep or at bedtime
q.d. ..... every day
q.m. ..... every morning
q.n. ..... every night
p.c. ..... after meals
p.r.n. ..... when necessary
q1 (2,3,4)h ..... every 1 (2,3,4,) hours
q.i.d. or 4 i.d. ..... four times a day
S.O.S. ..... once if necessary
stat ..... at once
t.i.d. ..... three times a day

Relating to Solutions

B.A. ..... boric acid solution
N.S.S. or N.S. ..... normal saline solution
S.S.E. ..... soap suds enema

Relating to Surgical Supplies

Abd ..... abdominal pad
D.S.D. ..... dry sterile dressing
F. sheet ..... Field sheet used to establish sterile field
4 x 4 ..... gauze dressing folded to 4 x 4 inches
2 x 2 ..... gauze dressing folded to 2 x 2 inches

Relating to Surgical Operation

O.P. ..... day of operation
D.O.S. ..... day of surgery
P.O.D. ..... post operative day
Pre-Op ..... before operation
Post-Op ..... after operation

Miscellaneous

c ..... with
C ..... centigrade
DU ..... diagnosis undetermined
et ..... and
etc ..... and so forth
F ..... Fahrenheit
Fr ..... French, denotes size of catheter or tube
s ..... without

MEDICAL TERMINOLOGY

Purpose

To help the corpsman gain understanding of what he reads in his patients' records and in medical literature.

Suggested Method of Study

1. Select a new word each day.
2. Look at it; break it down into its parts.
3. Write down what you think it means.
4. Check your answer with the definition in a medical dictionary.

EXAMPLE

Myocarditis
myo card itis
myo – muscle
card – heart
itis – inflammation of

Myocarditis: Inflammation of the muscles of the heart.

PREFIXES

Pertaining to the Body

brach- ..... arm
capit- ..... head
cardi- ..... heart
cholecyst- ..... gallbladder
cyst- ..... bladder
derma- ..... skin
entero- ..... intestines
glosso- ..... tongue
gastro- ..... stomach
hemo- ..... blood
hepat- ..... liver
laparo- ..... abdomen

pyro- . . . . . heat, temperature

SUFFIXES

Pertaining to Conditions of the Body

-algia . . . . . pain
-cele . . . . . tumor, hernia
-clysis . . . . . a slow injection of a large amount of fluid
-emia . . . . . blood
-esthesia . . . . . sensation
-itis . . . . . inflammation
-lith . . . . . stone, calculus
-mania . . . . . insanity
-oma . . . . . morbid condition, tumor
-opia . . . . . vision
-pathy . . . . . disease
-phobia . . . . . fear, or dread
-plegia . . . . . paralysis
-pnea . . . . . breathing
-ptosis . . . . . falling
-rrhea . . . . . flow, discharge
-scopy . . . . . visual examination, looking into
-therapy. . . . . treatment
-thermy . . . . . heat
-throphic, trophy.. growth, nutrition
-uric, uria . . . . . urine

Pertaining to Surgical Operations

-ectomy . . . . . removal of
-plasty . . . . . to form, or build up
-pexy . . . . . to fasten
-(o) stomy . . . . . creation of an opening
-(o) tomy . . . . . cutting into
-(o) rrhaphy . . . . repair of
-manometer . . . . used to measure pressure
-meter . . . . . used to measure
-scope . . . . . used to examine by looking into or by hearing

EXAMPLES FOR PRACTICE

1. Anemia
2. Anesthesia
3. Appendectomy
4. Atrophy
5. Blepharitis
6. Cholelithiasis
7. Claustrophobia
8. Colostomy
9. Cystotomy
10. Dyspnea
11. Endoscope
12. Enteroptosis
13. Glossitis
14. Gonorrhea
15. Herniorrhaphy
16. Hydrotherapy
17. Hypertrophy
18. Hypodermoclysis
19. Myoma
20. Nephropexy
21. Neuralgia
22. Polyuria
23. Psychopathic
24. Pyromania
25. Rectocele
26. Sphygmomanometer
27. Stethoscope
28. Thermometer
29. Thoracoplasty
30. Venoclysis

10311
149

Some Symptoms to be Observed and Terms to Use in Recording Them

Concerning	Observation	Term to Use
Abdomen	1. Hard, boardlike	1. Hard, rigid
	2. Soft, flabby	2. Relaxes, flaccid, soft
	3. Hurts when touched	3. Sensitive to touch
	4. Appears swollen, rounded	4. Protuberant
	5. Filled with gas	5. Distended, tympanites
Areas		1. Epigastric
		2. Right lumbar
		3. Umbilical
		4. Left lumbar
		5. Right iliac
		6. Hypogastric
		7. Left iliac
Amounts	1. Large amount:	
	of drainage	Profuse, copious, free
	of urine	Polyuria, measured in cc
	of defecation	Copious
	of emesis	Measured amount in cc
	2. Medium amount:	
	of drainage	moderate, usual
	of urine	measured amount in cc
	of defecation	moderate
	of emesis	measured amount in cc
	3. Small amount:	
	of drainage	Small, amount, scanty, slight very little
	of urine	Scanty, measured in cc
	of defecation	Small amount
	of emesis	Measured amount in cc
Appetite	1. Very fussy about food, refuses to eat many foods	1. Has definite likes and dislikes about food
	2. Eats all foods served	2. Appetite good
	3. Eats very little	3. Appetite poor
	4. Loss of appetite	4. Anorexia
	5. Craving for certain foods	5. List foods
	6. Refuses to eat	6. Refuses food (state reason)
Arm	1. Shoulder to elbow	1. Upper arm (right or left)
	2. Elbow to wrist	2. Lower arm (right or left)
Back (areas)	1. Upper back	1. Interscapular shoulder region
	2. Small of back	2. Lumbar region
	3. End of spine	3. Sacral region
	4. Gluteal region	4. Buttocks
Baths	1. Give when patient is admitted	1. Admission bath

21001031?

Figure 13-6.—Block diagram of the AN/ARC-52 receiver-transmitter.

the second mixer for heterodyning with the 21.85- to 31.75-mc injection frequency. The resulting final intermediate frequency of 1.85 mc feeds through a filter and four stages of amplification into a silicon diode detector, where it is demodulated and fed to the audio amplifier and into the headset.

The same oscillators and amplifiers (fig. 13-6) are used in transmitting except that a 1.85-mc oscillator replaces the IF stage of the same frequency and a separate preamplifier is used to drive the power amplifier. The initial 1.85-mc excitation is mixed in the first transmitter mixer stage with the 21.85- to 31.75-mc injection frequency. The 20.0- to 29.9-mc output is amplified and then mixed with the 200- to 370-mc injection frequency, producing the carrier frequency in the 225.0- to 399.9-mc range. This is fed through the preamplifier into the power amplifier where it is modulated and fed to the antenna.

Injection Oscillator

One of the representative circuits of interest is the A-bank crystal oscillator employed in conjunction with the injection amplifier. This oscillator, shown schematically in figure 13-7, generates a basic frequency of 24.9 to 33.9 mc in ten steps of 1.0 mc each. Tube VI is connected in a crystal-controlled, cathode-coupled circuit called a Butler oscillator. Oscillators of this type are characterized by good stability at relatively high frequencies and are capable of generating many different frequencies without the use of multiplying stages. The circuit permits operation of the crystal at an overtone frequency, which is an odd multiple of the fundamental crystal frequency.

1029

	4. Special attention or treatment	4. Special care to back, mouth, etc.
Chill	1. Blanket applied to help warm the patient	1. External heat applied (Method)
	2. Type as to severity	2. Severe, moderate, slight
	3. Duration	3. List number of minutes
Coma.....	1. Partly in coma	1. Partially comatose
	2. Deep in coma	2. Profound coma
Convulsion.....	1. Continuous shaking	1. Duration and description
	2. Shaking with intervals of rest	2. Duration and description
	3. Begin without warning	3. Sudden onset
Cough.....	1. Coughs at all times	1. Continuous cough
	2. Coughing over a long period of time	2. Persistent cough
	3. Coughs up material	3. Productive cough, describe material
	4. Short, hard cough	4. Hacking cough
Defecation.....	1. Bowel movement material	1. Feces, stool
	2. Bowel movement (act of)	2. Defecation
	3. Excessive defecation	3. Diarrhea, describe
	4. Gray colored liquid stool	4. Clay colored liquid stool
	5. Dark brown liquid stool	5. Highly colored liquid stool
	6. Formed, yet soft stool	6. Soft formed stool
	7. Formed with hardened stool	7. Hard formed stool
	8. Infrequent bowel movement	8. Constipation
	9. Black stool	9. Black, tarry stool
Dizziness.....	Dizziness	Vertigo
Drainage.....	1. Watery, from nose	1. Coryza
	2. Containing pus	2. Purulent
	3. Bloody	3. Sanguinous
	4. Consists of feces	4. Fecal
	5. Of serous fluid	5. Serous
	6. Containing mucus and pus	6. Mucopurulent
	7. Tough, sticky	7. Tenacious
	8. From vagina (after delivery)	8. Lochia
Dressings.....	1. A second dressing added to the first	1. Dressing reinforced
	2. Dressing removed, another applied	2. Redressed
	3. Drain tubes cut off	3. Drain tubes shortened (number of inches)
	4. Drain taken out	4. Drain removed
Drop.....	A drop or drops	Gtt/s

10314

Emesis.....	1. Produced by effort of patient	1. Induced
	2. Ejected to a few feet distant	2. Projectile
	3. If blood is only noticeable	3. Blood tinged
	4. Material vomited	4. Vomitus, emesis
	5. Contents	5. (Describe color, odor, appearance, consistency)
Eyes.....	1. Sharpness of vision	1. Visual acuity
	2. Yellow in color	2. Jaundiced
	3. Puffy	3. Edematous
	4. Motionless	4. Staring
	5. Sensitive to light	5. Photophobia
	6. Double vision	6. Diplopia
	7. Squinting	7. Strabismus
	8. Abnormal protrusion of eyeball	8. Exophthalmos
	9. Inflammation of conjunctiva	9. Conjunctivitis
Faint.....	Fainting	Syncope
Fever.....	1. Without fever	1. Afebrile
	2. Temperature above normal	2. Pyrexia
	3. Temperature greatly above normal	3. Hyperpyrexia
	4. Temperature suddenly returns to normal	4. Crisis
	5. Temperature gradually returns to normal	5. Lysis
Gas.....	1. Gas in the digestive tract	1. Flatus
	2. Having gas in the digestive tract	2. Flatulence
	3. Swelling of abdomen	3. Distention
Gums.....	Inflammation of the gums	Gingivitis
Hallucination.....	1. Of hearing	1. Auditory hallucination
	2. Of sight	2. Visual hallucination
	3. Of smell	3. Olfactory hallucination
	4. Of taste	4. Gustatory hallucination
Hands.....	1. Dirty, rough, nails broken	1. Shows lack of care
	2. Abnormally large	2. Massive
Head.....	1. Forehead	1. Frontal region
	2. Region over temple	2. Temporal region
	3. Back of head	3. Occipital region
	4. Base of skull	4. Basilar region
Hives.....	1. Hives	1. Urticaria
	2. Itching	2. Pruritus
Joints.....	1. Bending	1. Flexion

10315 10314

Joints — Continued	2. To straighten	2. Extension
	3. Turn inward	3. Inversion
	4. Turn outward	4. Eversion
	5. Revolve around	5. Rotation
	6. Move away from median line	6. Abduction
	7. Move toward median line	7. Adduction
Legs.....	1. Thigh to knee	1. Upper leg (right or left)
	2. Knee to ankle	2. Lower leg (right or left)
Lice.....	1. Head, body, pubic	1. Pediculi
	2. Condition of lousiness	2. Pediculosis
Mental attitude.....	All statements on charts concerning attitudes must have "appears", "seems", or "apparently" before them. These are the observer's interpretations of what he thinks he sees. Only the patient knows for sure what his attitude is.	
	1. Hard to please	1. Irritable, fault-finding
	2. Distrustful	2. Distrustful, suspicious
	3. Happy	3. Optimistic, cheerful
	4. Sad	4. Depressed, moody
	5. Afraid	5. Apprehensive, anxious
	6. Over religious	6. Deeply religious
	7. Lacks emotional control	7. Hysterical
	8. Loss of memory	8. Amnesia
Nourishment.....	1. Very small amount of water	1. Sips water
	2. Small pieces of ice	2. Chopped ice
	3. Drink of water	3. Water (number of cc)
	4. Given through tube into stomach	4. Gavage
	5. Given by enema	5. Nutritive enema, (fluid and amount
Odor.....	1. Not unpleasant	1. Agreeable
	2. Spicy	2. Aromatic
	3. Like fruit	3. Fruity
	4. Very unpleasant	4. Offensive
	5. Belonging to particular drug, etc.	5. Characteristic
	6. Like feces	6. Fecal
Pain.....	1. Great pain	1. Severe
	2. Little	2. Slight
	3. Period of great pain followed by period of little or no pain	3. Paroxysmal
	4. Spreads to distant areas	4. Radiating
	5. Started all at once	5. Sudden onset
	6. Hurts worse when moving	6. Increased by movement
Paralysis.....	1. Of the muscles of the face	1. Facial
	2. Of the legs	2. Paraplegia

10010316

Paralysis — Continued	3. Of one side of body	3. Hemiplegia
	4. Of a single limb	4. Monoplegia
	5. Both arms and legs	5. Quadriplegia
Patient (admission of).....	1. Walking	1. Ambulatory
	2. Carried (infant)	2. In arms
	3. By wheelchair	3. Per wheelchair
	4. By stretcher	4. Per stretcher
	5. Had a bedsore when admitted	5. Decubitus ulcer present on admission; (describe size and appearance)
Perspiration.....	1. Large amount	1. Profuse diaphoresis
	2. Small amount	2. Scanty
Pulse.....	1. Number of beats per minute	1. Rate
	2. Rhythm	2. Regular or irregular
	3. Beats missed at intervals	3. Intermittent
	4. Over 100 beats per minute	4. Rapid
	5. Very rapid, beats indistinct	5. Running
	6. Slow in rate	6. Slow
	7. One scarcely perceptible	7. Thready
	8. Small, rapid and tense	8. Wiry
Reproductive organs.....	External reproductive organs	Genitalia (external)
Respiration.....	See breathing	
Restraint.....	1. Boards put on bed	1. Sideboard applied
	2. Tied down with sheet	2. Sheet restraint applied
	3. Fastened to bed with ankle strap (right)	3. Right ankle strap applied
Rings.....	1. Rubber ring to relieve pressure	1. Placed on rubber ring
	2. Cotton rings applied under heels, elbows, etc.	2. Cotton ring applied to each heel, elbow, etc.
Skin.....	1. Normal	1. Healthy
	2. Pink, hot	2. Flushed
	3. Blue in color	3. Cyanotic
	4. Very white	4. Extreme pallor
	5. Shines	5. Glossy
	6. Raw surface	6. Excoriation
	7. Yellow in color	7. Jaundiced
	8. Torn	8. Lacerated
	9. Containing colored areas	9. Pigmented
	10. Wet	10. Moist
	11. Scraped	11. Abraded
	12. Black and blue mark	12. Ecchymosis
	13. Cold, clammy	13. Cold, clammy
Sleep.....	1. Slept very little	1. Slept very little or slept at short intervals

1160317

Sleep — Continued	2. Tired when wakens 3. Moans while sleeping 4. Inability to sleep	2. Awakens fatigued 3. Sleeps disturbed—moaning 4. Insomnia
Smoke.....	Smokes too much	Smokes excessively
Unconsciousness.....	1. Complete unconsciousness 2. Partial unconsciousness 3. Pretended unconsciousness	1. In comatose condition 2. In stuporous condition 3. Feigns unconsciousness
Urination.....	1. To urinate 2. No control over urination 3. Burning when voiding 4. Large amount of urine voided 5. Total suppression of urine 6. Frequent voiding at night 7. Painful urination 8. Pus in urine 9. Blood in urine 10. Hemoglobin in urine 11. Glucose in urine 12. Albumin in urine 13. Acetone in urine 14. Bile in urine 15. Scantiness of urine 16. Sugar in urine	1. Void, urinate 2. Involuntary, incontinent 3. Burning sensation on urination 4. Polyuria 5. Anuria 6. Nocturia 7. Dysuria 8. Pyuria 9. Hematuria 10. Hemoglobinuria 11. Glucosuria 12. Albuminuria 13. Acetonuria 14. Choluria 15. Oliguria 16. Glycosuria
Vomit.....	Desire to do so (for various types, see Emesis)	
Weight.....	1. Overweight 2. Thin, underweight	1. Obese 2. Emaciated
Wounds.....	1. Deep 2. Slight, surface only 3. Not infected 4. Discharging pus 5. Infected 6. Torn	1. Deep 2. Superficial 3. Clean 4. Suppurating 5. Infected 6. Lacerated

10318

CHAPTER 12

GENERAL WARD NURSING METHODS AND CARE OF PATIENTS

OBSERVATION OF THE PATIENT

Of all the patient's medical attendants the hospital corpsman is with him most constantly. For this reason the quality of his observation and reports, written and oral, are of utmost importance.

The doctor depends upon the corpsman for accurate recognition, recording, and reporting of the patient's mental and physical condition during the day and night. It is important to be able to recognize even the slightest change in the patient because while the change is slight in itself, when combined with other changes it may show a definite disease process indicating need for further treatment.

The recording of observations should be done as soon as possible after they have been made. Do not wait until the end of the day because by that time you may forget a detail which is important in the treatment of your patient. Use medical terminology in your recording, but if you are in doubt as to the correct term, use plain English.

Purposes

Observation is essential at all times, from the patient's admission until his discharge, and particularly during bath and meal times, while asleep and during treatments and visiting hours.

1. To aid the doctor in making a diagnosis and prescribing treatment for the patient.

2. To determine the effects of a prescribed course of treatment.

3. To modify the nursing care to fit the needs of the patient.

Signs and Symptoms

Indications of the mental and physical condition of the patient may be classified as OBJECTIVE AND SUBJECTIVE symptoms.

OBJECTIVE SYMPTOMS are those which the observer can see, such as rashes, swelling, and inflammation; can feel, such as skin eruptions, masses, and changes in pulse; can hear, such as speech and snorting respiration; can smell, such as odors.

SUBJECTIVE SYMPTOMS are those which only the patient can feel or describe, such as pain, tenderness, ache, and nausea.

ADDITIONAL SIGNS indicating the condition of the patient may be determined by the use of instruments, examinations, and tests, such as thermometers, manometers, X-rays, and specimens.

Learning to recognize signs and symptoms of the patient (those he tells you, those you see, feel, hear and smell, and those you may infer by his actions and attitudes) takes time and experience. Learn to observe your patient using these questions:

1. What am I seeing, feeling, hearing, smelling?
2. How is it affecting my patient?
3. Who should receive the report of these observations?
4. When should I report?
5. Where should I record?
6. What can I do about it?

ASSISTING WITH A PHYSICAL EXAMINATION

Purpose

1. To aid the doctor in making a diagnosis and planning therapy.

10319

2. To aid the corpsman in planning the necessary nursing care.

Equipment

Tray with—

1. Diagnostic set (ophthalmoscope, otoscope)
2. Tongue depressors
3. Flashlight
4. Stethoscope
5. Sphygmomanometer
6. Tape measure
7. Rubber gloves or finger cots
8. Skin pencil
9. Percussion hammer
10. Paper bag for used depressors
11. Curved basin for specula
12. Safety pins
13. Paper towels

Procedure

1. Place patient in a warm, well-lighted room or screened area.
2. Tell the patient what is to be done and how he may help. (If a female patient is being examined another female must be present.)
3. Undress and cover the patient with a sheet.
4. Take and record height and weight. (Place paper towel on scale.)
5. Place patient in horizontal position.
6. Have all equipment at hand.
7. Assist the doctor as necessary, placing patient in proper position for the examination desired (fig. 12-1). Doctor will usually examine patient's head first then proceed to chest, abdomen, extremities and genitalia. Expose each part of the body as the examination progresses.

After Examination

1. Make patient comfortable in bed.
2. Strip, clean and reset tray.

CHECK-LIST FOR OBSERVATIONS

OBSERVING THE PATIENT

General Appearance

Is he short? Stout? Thin? Average build? Does he appear in pain? Ill? Well? Does he Walk normally? With a limp?

Behavior

Does he appear happy? Worried? Excited? Depressed? Restless? Unconscious?

Does he refuse to talk or eat? Does he shout or sing?

When he talks, do his thoughts appear connected or does he ramble? Does he lisp, stutter, stammer?

Does he appear gloomy? Aggressive? Friendly? Cooperative? Bored? Homesick?

Does he sleep well? Poorly? Is he restless in his sleep? Does he moan, groan, or cry out in his sleep?

How does he act toward the other patients? Ward personnel? His visitors?

Does he join in ward activities?

Position

Does he stay in one position in the bed? On his side or his back? Does he draw his legs up on his abdomen?

Does he have difficulty breathing when he lies down?

Is his neck stiff? Arched backward?

Is he able to move about in bed?

Is he comfortable?

Have you changed his position in the past 2 hours?

Skin

Is it clean? Hot? Cold? Dry? Moist?

Is the skin flushed? Pale? Cyanotic?

Are there any scars? Wounds? Rashes? Scratches? Bruises? Lumps?

Are there any signs of pressure? Redness? Breakdown? Spots of various colors?

Does the skin appear shiny? Stretched? Is there edema present?

Is a pit made when the fingers are pressed into the skin?

Are there lice? Nits?

Does he perspire profusely?

When is the last time you gave him special skin care?

Eyes

Are the eyelids swollen, bruised or discolored?

Are the whites of the eyes clear? Dull? Yellow? Bloodshot?

Are the pupils contracted? Dilated? Equal in size?

1032

SIMS—Used for rectal, vaginal and perineal examinations and treatments

DORSAL RECUMBENT—Used for examination of external genitalia; urethral, vaginal and rectal treatments

DORSAL LITHOTOMY—Used for examination of external genitalia; urethral, vaginal and rectal treatments

SHOCK or TRENDELENBERG—Used in treatment of shock; pelvic and abdominal surgery. Blocks also used for orthopedic patients in traction

LUMBAR PUNCTURE—Used for lumbar puncture. Important—Hips and shoulders must be in the same vertical plane

MODIFIED JACK KNIFE—Used for rectal examination and treatment. Legs may hang down straight

POSTURAL DRAINAGE - GATCH BED—Used to promote drainage from respiratory tract. Patient is placed over knee break of bed

POSTURAL DRAINAGE - STOOL METHOD—Used to promote drainage from respiratory tract

Figure 12-1.—Positions for examinations and treatments.

1032101

Does he complain of pain? Burning? Too much light?

Is there a discharge from his eyes? Tears?

Ears

Do the ears appear normal?

Does he seem to hear well?

Does he complain of buzzing or ringing in his ears?

Does he have any discharge from his ears? What kind it is?

Does it have an odor?

Mouth

Does his tongue appear dry? Moist? Clean? Coated? Cracked? Red? Spotted?

Does he complain of an unpleasant taste? Is there an odor to his breath?

What kind of an odor?

Are his teeth in good repair? Clean? Does he have removable bridges? Dentures?

Does he have any sores in his mouth? What do they look like?

Does he complain of any soreness?

When was the last time you gave him special mouth care?

Nose

Does his nose appear straight?

Does he appear to have difficulty breathing through his nose?

Is there any nasal discharge present?

Chest

Are there rattling, snorting, or wheezing sounds when he breathes?

Does he have pain or difficulty breathing?

Is he coughing? Is the cough productive? Dry? Hacking? Persistent?

Is sputum expectorated? Is it white? Yellow or rusty? Thick or thin? Large or small amount? Does it have an odor? What kind of odor?

Abdomen, Bowels, and Bladder

Is the abdomen distended? Is the distention above or below the umbilicus or over the entire abdomen?

Does he belch?

Is he nauseated?

Is he vomiting? Is pain or nausea associated with it? How often does he vomit?

What does the vomitus look like? Color? Odor? Amount? Contents?

Has he had a bowel movement? When? Is he constipated? Does he have diarrhea? Is he incontinent? What is the color, consistency, amount and odor of the feces? Is there blood, pus or worms in the feces?

Does he void sufficiently? Does he void frequently in small amounts? What is the color, odor and amount of the urine? Is there blood or sediment in the urine?

Does he have difficulty or discomfort passing urine? Burning in urination?

Does he void involuntarily?

Intake

Is he thirsty? Is he drinking enough water? Fruit juices?

Is his drinking water fresh? Can he reach it? Does he have a drinking tube?

Is he on forced or restricted fluids? Is there an Intake and Output sheet with a pencil at his bedside? Have you instructed him on how to keep his record?

Is he receiving an intravenous infusion? Have you checked recently?

Is he eating all his food? Is the tray attractive? Are the dishes and silverware clean?

Is he in the best position to eat? Does he need help? Can he reach his food?

Is he on nothing by mouth? Is a sign posted on his bed to that effect?

Pain

Does he have pain/ache? Where is it?

How long has he had it? How severe is it? Is it sharp, dull, aching, cramping, knife-like?

Is the pain constant? Intermittent?

Is he nauseated with the pain?

Does he assume a special position to relieve the pain?

Does he have a medication ordered to relieve the pain? When was the last time he had the medication? Did the medication relieve him?

Has the pain and its description been reported and recorded?

10322

Figure 13-7.—A-bank crystal oscillator.

The crystal (fig. 13-7) is connected between the cathodes of a twin-triode tube. The proper crystal and associated tuning inductance are selected by the mechanical tuning unit. The circuit consists of a grounded-grid amplifier and a cathode follower. The crystal is used as a series-resonant wave filter which couples feedback from the cathode follower to the input of the grounded-grid amplifier. The crystal also determines the frequency of the feedback signals.

The grounded-grid amplifier supplies the energy necessary for sustained oscillation in the resonant circuit composed of L1 and associated capacitance. The action of the feedback circuit is such that if the cathode of the grounded-grid amplifier swings positive, a positive pulse is returned to it. When the cathode swings negative, a negative pulse is returned, thereby meeting the necessary conditions of feedback for sustained oscillation.

The action of the feedback loop in the Butler oscillator (fig. 13-7) takes place in the following sequence. Assume that the grounded-grid amplifier is conducting and that the cathode is swinging more positive. This decreases tube conduction and causes the plate voltage to swing in the positive direction. This voltage change is coupled through C2 to the grid of the cathode follower, where the plate current is increased and the cathode is driven to a higher positive potential. The positive swing at the cathode is coupled through the crystal to the cathode of the grounded-grid amplifier. This completes the feedback circuit and applies energy to the tube in such polarity as to sustain oscillation in the tuning circuit.

The output of the A-bank oscillator is coupled to a mixer stage where it is heterodyned with a signal from the B-bank oscillator (2.15 to 3.05 mc) to produce an injection signal of 21.85 to 31.75 mc.

Audio Input

Referring to the block diagram (fig. 13-6), note the blocks associated with the transmitter power amplifier. These circuits are the microphone input stage, the modulator, and the sidetone audio stage, all of which are included in the transmitter audio system.

Figure 13-8 is a simplified schematic showing the microphone input stage, using a dynamic microphone input.

1030 esbi

Wounds

What is the condition of the wound? Is it clean? Reddened? Swollen? Painful?

Is a discharge present? What is its color? Odor? Consistency? Is it bloody?

Does he have a dressing? Does it need changing?

Patient's Bedding

Does he have enough covers? Too many?

Is his bed linen clean? Wrinkled? Wet? Soiled?

Is the bottom sheet tight and smooth?

Are the top covers light and loose?

Appliances and Apparatus

Does the patient require an air ring, sandbags, bed cradle, extra pillows for support or comfort? Does he have them? Are they positioned correctly?

Does the patient have a cast? Is there pressure anywhere? Are there rough edges on the cast?

Is the cast dry? Are there cracks in the cast?

Is the patient in traction? Are the weights hanging free?

Is the patient up in bed?

Is the rope in the pulley groove? Is the traction pulling in the desired way?

Is the frame causing pressure? Is the frame well padded?

Is his foot or hand supported?

The preceding questions have all been in relation to the patient himself, now consider his environment.

OBSERVING THE WARD

General Appearance

Does the ward look clean? Orderly? Pleasant?

Noise

Is the ward noisy? Is there loud talking, laughing?

Ventilation

Is the air fresh? Stale? Are there odors?

Temperature

Is it hot and stuffy?

What does the wall thermometer read?

Is the ward warm enough for the patient's bath?

Is the ward cool enough for comfortable sleeping?

Is the patient in a draft?

Lights

Are they glaring? Bright enough? Shaded?

Are they shining in the patient's eyes?

Patient's Unit

Is the unit clean, orderly? Complete?

Is his bedside stand within his reach?

Is his signal cord within his reach?

CARDINAL SYMPTOMS OR VITAL SIGNS

Temperature (T), pulse (P), respiration (R), and blood pressure (BP) are called the cardinal symptoms or vital signs because they give important and vital indications of the condition of the patient. Changes in cardinal symptoms, typical of certain diseases and certain stages of diseases, are so important that a special sheet is maintained to record them. The measurement of these symptoms aids the doctor in making a diagnosis and prescribing treatment, and the corpsman in determining the kind and amount of nursing care necessary.

TEMPERATURE

Temperature is the degree of heat in the body. It is the balance between heat produced and heat lost by the body. When the balance is disturbed, deviations of body temperature result. Deviations above the normal range are called elevations or fever; those below normal range are subnormal.

Normal Temperature

(The normal range is 97 to 99 degrees F. (mouth); 98 to 100 degrees F. (rectum); 96 to 98 degrees F. (axilla). The normal temperature is usually at its lowest point in the early morning and at its highest in the late afternoon.

10323

Fever

Fever may begin suddenly or gradually and its course may be constant, remittent or intermittent (fig. 12-2).

A CONSTANT FEVER is one in which the temperature remains elevated at about the same level during a period of 24 hours or longer.

A REMITTENT FEVER is one in which the temperature rises and falls in a moderate range but does not approach normal.

An INTERMITTENT FEVER is one in which the temperature rises and falls in a great range, approaching normal or below in a 24 hour period.

Subnormal

Due to shivering mechanism of the body, this type of temperature is not often encountered except in certain periods of extreme illness when the subnormal temperature would indicate body resistance is being overwhelmed. It is also found in many chronically ill, starving, cachectic or emaciated patients.

BODY TEMPERATURE is measured by the clinical thermometer. The thermometer is scaled in the Fahrenheit system and calibrated in 2/10 degrees (fig. 12-3).

ROUTES OF MEASUREMENT

1. By MOUTH which is the easiest and most often used route. The thermometer is left in place 3 minutes.
2. By RECTUM which is the most accurate, and is used for children, delirious or unconscious patients, and patients who are mouth breathers, who cough frequently, or those who have had mouth surgery. The thermometer is held in place 5 minutes.
3. By AXILLA which is least accurate and used only when mouth and rectal routes cannot be used. The thermometer is held in place 10 minutes.

Shaking Down the Thermometer

1. Stand in clear space away from bedside table.
2. Hold thermometer firmly at top between thumb and first two fingers (fig. 12-4).
3. Shake with loose wrist movement as though shaking water off the hand.
4. Shake thermometer down to 95 degrees F. or below.

Reading the Thermometer

1. Stand in a good light.
2. Hold thermometer at the stem end, ridge side toward you (fig. 12-5).
3. Read the scale to the nearest 2/10 of a degree, i.e., 98.6.

PROCEDURE FOR TAKING TEMPERATURE, PULSE, AND RESPIRATION

Purpose

To determine the degree of temperature, the rate and characteristic of the pulse and respiration of the patient or group of patients.

Equipment

Tray with:

2 covered containers of isopropyl alcohol 70 percent, or isopropyl alcohol 70 percent with 0.5 percent iodine

Figure 12-2.—Types of fever.

10324

Figure 12-3.—Types of thermometers; (1) oral; (2) rectal.

Figure 12-4.—Shaking down the thermometer.

Figure 12-5.—Reading the thermometer.

6 thermometers—3 in each container of alcohol
1 container of water
1 container of tincture of green soap solution
1 container of cotton squares
1 sputum cup of waste cotton
1 clock or watch with a second hand
1 TPR book
1 pen or pencil

NOTE: Benzalkonium chloride or liquid iodine-type disinfectant may be the solution of choice for thermometers at your station. If used, omit soap solution.

NOTE: At some stations individual thermometers are provided for each patient.

Precautions

1. Have the patients lying quietly in beds or sitting down in chairs.

Wait for 30 minutes before taking the temperature of a patient who has had a hot or cold drink or has been smoking.

3. Be sure the thermometer is down to 95° F. before placing it in the patient's mouth.

4. Be sure the thermometer is under the patient's tongue.

5. Wipe thermometer with moistened cotton before and after use. The important step in cleaning a thermometer is the mechanical action of rotary motion when wiping.

Procedure

1. Remove a thermometer from the first container of alcohol.

2. With a cotton square and in a rotary motion, wipe the thermometer from stem to bulb. (Fig. 12-6). Shake down thermometer to 95°F.

Figure 12-6.—Wiping off the thermometer.

3. Place thermometer under the first patient's tongue; caution him to keep his lips closed.

4. Distribute the other thermometers to the second and third patients in the same manner.

5. Take the pulse and respirations of the third patient. Record in book.

6. Repeat step 5 for the second and first patient.

10325

7. Remove the thermometer from the first patient's mouth.

8. Moisten cotton square with soap solution; wipe the thermometer from stem to buld in a rotary motion.

9. Moisten a cotton square with water; wipe the thermometer from stem to bulb in a rotary motion.

10. Read the thermometer and record reading in the book.

11. Place the thermometer in the original alcohol container.

12. Repeat steps 8 through 11 for the second and third patients.

13. Remove the thermometers from the second alcohol container.

14. Repeat steps 2 through 12 for the next three patients.

15. Continue alternate use of the thermometer containers until all patients' temperatures have been taken.

16. Record temperature, pulse, and respiration on SF 511 of each patient's chart. Describe abnormal characteristics of pulse and respiration in Nursing Notes.

Care of Equipment

After each use—

1. Remove waste.
2. Reset tray.
3. Stow in proper place.

Daily—

1. Wash all containers and tray in hot soapy water, rinse, and dry.
2. Wash each thermometer in cool soapy water; rinse under running water; dry.
3. Refill and reset tray.

TAKING RECTAL TEMPERATURES

Equipment

Tray with—

Rectal thermometer in container of isopropyl alcohol, 70%
Container soap solution
Container cool water
Container cotton squares
Sputum cup for waste
Water soluble lubricant on tissue

Precautions

1. Wait for 30 minutes after the patient has had an enema.
2. Use only a stub bulb thermometer expressly made for rectal use.
3. Be sure to lubricate the thermometer.
4. Hold the thermometer in place.

Procedure

1. With cotton square wipe down thermometer.
2. Shake down and lubricate thermometer.
3. Turn patient on his side.
4. Insert thermometer about 1-1/2 inches into rectum in an upward and forward direction.
5. Hold thermometer in place 5 minutes.
6. Remove thermometer.
7. Moisten cotton with soap solution, wipe down thermometer; repeat, using water.
8. Read thermometer; record temperature in book. Then place thermometer in container of alcohol.
9. Take pulse and respiration.
10. Record "R" (for rectal) above temperature in book and on patient's chart. WASH YOUR HANDS.

TAKING AXILLARY TEMPERATURES

Equipment

Same as for an oral temperature plus hand towel.

Precautions

1. Be sure the axilla is dry.
2. Be sure the arm is pressed closely to the body (fig. 12-7).

Procedure

1. Wipe axilla dry.
2. Place the thermometer in axilla. Have patient grasp his opposite shoulder and press his arm against his body.
3. Leave in place 10 minutes.
4. Proceed as in Oral Temperature instructions.
5. Record "A" (for axillary) above temperature in book and on patient's chart.

PULSE

Pulse is the alternate contraction and dilation of the arteries due to the pumping of the

10326

Figure 12-7.—Taking an axillary temperature.

blood by the heart. Changes in the character of the pulse may be due to any factor which interferes with the function of the heart, the volume of the blood, and the elasticity of the blood vessels. Therefore, the measurement of the pulse is a valuable means of learning the condition of the heart, blood vessels, and general condition of the patient.

Normal Pulse

The pulse rate even in good health varies with the individual. The rate is faster in infants and young children, slower in aged persons, faster in women than in men, and is affected by exercise, fatigue, and emotions. The normal range for adult women is 72 to 80; for adult men 62 to 72 pulsations per minute. The pulse rate usually increases 10 beats for each degree rise in temperature. The normal pulse should feel firm, smooth, straight, and elastic under the fingertips and should be regular in rate and rhythm.

The pulse may be taken wherever an artery lies near the surface of the body or over a bone. The most frequently used site is the radial artery on the thumb side of the wrist. Other arteries which may be used:

1. Temporal—side of the head in front of the ear.
2. Carotid—front side of neck, may often be seen beating.
3. Dorsalis pedis—the top of the foot.

Measurement of Pulse

1. The pulse rate—number of beats per minute.
2. The force—strength or weakness of beat.
3. The rhythm—regular or irregular space between beats.
4. The volume—full or soft.

The pulse is usually taken at the same time the temperature is taken and whenever the patient shows a change in condition, postoperatively while recovering from anesthesia, when getting out of bed for the first time, and when receiving medication affecting the pulse.

Variations of Pulse

1. Normal—regular rate, rhythm, force, and volume.
2. Missed beat—regular omissions in rhythm and rate; may be irregular in force and volume.
3. Intermittent—irregular rhythm and rate; may be irregular in force and volume.
4. Thready—rapid, running, difficult to count or to determine quality (fig. 12-8).

RESPIRATION

Respiration is the act of breathing in (inhaling) and breathing out (exhaling) air by the lungs. Oxygen is needed by the body; the act of respiration supplies this need.

Normal Respiration

The normal respiration is regular in rate, rhythm, and depth and is performed without pain, strain, or difficulty. The normal rate is rapid in young children, slow in aged persons; ranges from 16-24 per minute in healthy adults and is affected by age, sex, exercise, sleep, and emotional disturbances. The respiration

Figure 12-8.—Variations of pulse.

40327

usually increases 1 to 2 in rate with every 10 beats rise in pulse and each degree rise in temperature. The respiratory movements are more or less under the patient's control and therefore should be counted without his knowledge. To do this keep the fingers upon the pulse as though still counting it, at the same time watching the rise and fall of the patient's chest, thus counting the respiration for a full minute.

Variations of Respirations

DYSPNEA—painful, difficult breathing, usually accompanied by sounds.

AIR-HUNGER—short, gasping breaths followed by a few normal breaths; cycle is repeated.

STERTOROUS—loud, snorting breathing.

EDEMATOUS—moist sounds as if air is passing through water.

CHEYNE-STOKES—gradual increase in depth of respirations until dyspnea is reached; followed by decrease until breathing ceases for few moments; then the cycle is repeated.

APNEA—a condition in which there is a temporary cessation of breathing.

ORTHOPNEA—inability to breath lying down.

Taking Pulse and Respiration

1. Have patient lie or sit down. Place his arm and hand in a relaxed position, thumb up, supported on a chair arm, table, bed or place across his chest.
2. Locate pulse by placing 3 fingers (not your thumb) on the thumb side of patient's wrist.
3. Count pulse rate for 30 seconds, multiply by 2, and record as number of beats per minute. Check again, noting the quality (force, rhythm, volume). If any deviation is noted, take pulse for full minute.
4. With fingers still on wrist, count respirations for 30 seconds; multiply by 2 and record as number of respirations per minute. If any deviations are noted, count respirations for full minute.

BLOOD PRESSURE

Blood pressure is the force that the blood exerts against the walls of the vessels through which it flows. The blood pressure is commonly meant to be the pressure in the arteries. The pressure in the arteries varies with the contraction (work period) and the relaxation (rest period) of the heart. SYSTOLIC PRESSURE—when the heart contracts, the blood in the arteries is at its greatest pressure. DIASTOLIC PRESSURE—when the heart relaxes, the blood in the arteries is at its lowest pressure. PULSE PRESSURE is the difference between systolic and diastolic pressures.

Normal blood pressure.—A systolic pressure of 110 to 136 millimeters of mercury and a diastolic pressure of 60 to 90 mm may be considered as being within the normal range. The pulse pressure is usually about one half the diastolic pressure.

PROCEDURE FOR TAKING A BLOOD PRESSURE READING

Purpose

To determine the systolic and diastolic blood pressure in the brachial artery. To determine the pulse pressure.

Equipment

Stethoscope
Sphygmomanometer
Alcohol sponges.

Precautions

1. Explain procedure to the patient to lessen his fears or apprehension.

Figure 12-9.—Blood-pressure apparatus (Sphygmomanometer, Aneroid and Mercury type).

escol 10328

2. Patient must be at rest, lying down in bed or sitting quietly in a chair with the arm to be used well supported.

3. Be sure the cuff of the apparatus is completely deflated and the indicator registers zero before starting the procedure.

4. Wipe the bell and earpieces of the stethoscope with an alcohol sponge before starting the procedure.

5. When repeated readings are ordered, the same arm should be used and the same person should carry out the procedure.

Procedure

1. Push patient's sleeve well above his elbow; if sleeve is tight, remove it.

2. Starting with the wide portion of the cuff, wrap it snugly and smoothly around the arm above the elbow. Tuck narrow end under the previous turn.

3. Clip indicator on the cuff (aneroid type), or place apparatus on a level surface (mercury type).

4. With the fingers, locate the brachial pulse at the bend of the elbow.

5. Place the stethoscope in the ears, earpieces facing forward.

6. Place the bell of the stethoscope over the spot where the brachial pulse was felt.

7. Tighten thumb screw of the valve.

8. Holding the stethoscope in place, inflate cuff with the bulb until the indicator reads 200 mm. or to 20 mm. above where the sounds are no longer heard.

9. Loosen the thumb screw of the valve to allow the air to escape slowly.

10. Listen for the sounds, watch the indicator and note the number on the indicator where the first distinct rhythmic sound is heard. This is the SYSTOLIC PRESSURE.

11. Continue releasing air from the cuff and note the number on the indicator at which the sound changes to a dull muffled beat. This is the DIASTOLIC PRESSURE (fig. 12-10).

12. Open the valve completely, releasing all the air in the cuff.

13. Repeat steps 3 through 12 to recheck.

14. Remove the cuff from the arm; roll cuff from the narrow to wide portion and place it in its case. Be sure the tubing is not pinched or kinked.

15. Wipe earpieces and bell of stethoscope with an alcohol sponge.

Figure 12-10.—Dial of spring manometer.

16. Record the systolic pressure over the diastolic pressure on the TPR sheet (SF 511) or graph on the Plotting Chart as directed.

PROVIDING FOR THE PATIENT'S COMFORT

In promoting the physical comfort of a patient it should be remembered that his mental attitude has a marked influence on his physical condition. Consequently, it must never be forgotten that a sick person reacts differently than a well one and is affected by things that ordinarily would not be noticed. Therefore, comfort is the enjoyment of physical and mental well-being. This applies to the corpsmen as well as to the patient.

One of the essentials of physical comfort is good posture. Good posture is the position of the body in correct alignment when standing, sitting, lying down, or in any phase of activity. The coordinated use of the body parts to produce motion and maintain equilibrium is termed body mechanics. The use of good posture and proper body mechanics by the corpsman when taking care of his patient will serve to:

1. Conserve the energy of the corpsman.

2. Promote the efficient use of muscles by the corpsman.

3. Avoid backstrain and fatigue of the corpsman.

10329

4. Teach his patient, by example, the importance of good posture.

The maintenance of good body alignment of the patient while in bed will serve to:

1. Promote the proper functioning of the body systems.
2. Promote a feeling of well-being.
3. Avoid fatigue and prevent deformities.

Providing for the mental comfort of the patient includes:

1. Adequate explanation of what is to be done.
2. Anticipating his wants.
3. Listening to his problems and referring him to the proper person or department when necessary.

These are but a few of the ways of providing for the mental comfort of the patient. The corpsman, by experience, will learn to recognize the general reactions of individuals, what causes people to behave the way they do, and to use these experiences in providing more complete care for his subsequent patients.

Principles of Moving and Lifting

The following principles may be applied to any moving or lifting activity as well as to moving and lifting the patient.

1. Place your body in correct alignment before starting the activity.
2. Place your feet far enough apart to provide an adequate base of support and to maintain balance.
3. Hold the object to be carried as close to the body as possible so that the centers of gravity of both will be close together.
4. Use the large muscle groups to lessen strain and fatigue.
5. Stoop to working level, keeping the back straight.
6. Slide, rather than lift a patient or object whenever possible.
7. Give adequate support to the object or body to be moved. Obtain help when moving a heavy object or unmanageable patient.
8. Work in unison, give signal before starting activity.

Methods of Moving and Lifting

1. Tell the patient exactly what is to be done and how he may help.
2. Bring all needed equipment to the unit.
3. Lock the wheels of the bed.
4. Fold all bedding and clothing so that the patient will not be hampered by them and yet will not be exposed.

Assume the Correct Position

1. Stand, facing in the direction of the move to be made, with the feet apart, one foot well in front of the other.
2. Stoop to working level by flexing knees, keeping back straight. (fig. 12-11).

Figure 12-11.—Body in correct position for moving or lifting.

3. Place arms under patient, keeping your elbows close to the body.
4. Set pelvis by tensing the abdominal and gluteal muscles simultaneously.

Move on Lift Patient by Shifting Own Weight From One Foot to the Other (Fig. 12-12).

1. To move patient toward you, let arms holding the patient slide on the bed; shift your weight from front to rear foot.

Figure 12-12.—Body in motion when moving or lifting.

2. To move the patient away from you, let arms holding the patient slide on the bed; shift your weight from the rear to the front foot.

10330

3. To lift the patient, keep elbows close to your body, straighten knees, equal weight on both feet.

4. To lower patient, keep elbows close to your body, flex knees to working level, equal weight on both feet.

To Move a Patient Up in Bed When He Is Able to Assist

Assume the correct position at side of bed. Ask patient to flex his knees and to grasp rungs at head of bed. Place one arm under patient's shoulders and one under the buttocks. At corpsman's signal, patient pushes with his heels, straightens knees, flexes elbows. Corpsman assists by shifting own weight from rear to front foot (fig. 12-13).

Figure 12-13.—To move a patient up in bed when he is able to assist.

To pull up a mattress, grasp underside of mattress, flex knees to working level and use the same method.

To Help The Patient Sit Up in Bed

Assume the correct position at side of bed. Slip near arm under patient's near shoulder. Ask patient to place his arm into same position on your shoulder. Use other arm as support for patient's head. Give signal, raise patient by shifting own weight from front to rear foot. (See fig. 12-14.)

To Turn a Patient on His Side

Assume the correct position at side of bed toward which patient is to be turned. Flex patient's knees. Place your hands on patient's far shoulder and hip. Slowly and gently turn patient toward you by shifting own weight from the front to the rear foot. Check patient's shoulder alignment.

Figure 12-14.—To help the patient sit up in bed.

To Move a Helpless Patient Up in Bed (Two Corpsmen)

A corpsman assumes the correct position on each side of bed. Flex patient's knees, ask him to make himself rigid. Both corpsmen slide arms under patient's head and shoulders and under patient's buttocks—lock wrists. At one corpsman's signal both move patient by shifting their weight from rear to front feet.

To Help the Patient Sit Up on Side of Bed

Dress patient in pajamas. Fanfold covers to foot of bed. Flex patient's knees; turn him on his side. Assume the correct position. Place one arm under patient's shoulder, the other behind the knees with hand under his lower thigh. Ask patient to place his hands around your neck or on your shoulders. Give signal; slowly

10330
10331

bring patient to sitting position by straightening your knees as you shift weight from front to the rear foot. Support patient's feet on stool or chair.

To Help The Patient Out of Bed Into Chair

Place chair parallel to bed. Bring patient to a sitting position on side of bed. Dress him in bathrobe and slippers. Allow patient to sit on side of bed until he is accustomed to this position. Assume the correct position in front of patient. Ask patient to place his hands on your shoulders. Place a hand on each side of the patient, midway between his axilla and hip. Supporting patient, allow him to slide off bed and stand on floor. Pivot with patient, lower him into chair by flexing your knees, shifting weight from rear to front foot, keeping your back straight.

To Help the Patient into Wheel Chair

Place chair against bedside table or have another corpsman hold it. Fold back foot rests. Follow instruction under To Help the Patient Out of Bed to a Chair. Assume the correct position of deep knee and hip flexion to adjust foot rests. For wheel chairs with adjustable knee rests, fold back knee rests until patient is seated, then adjust them.

To Move Patient From Bed to Stretcher

Place stretcher at right angles to the bed. Three corpsmen assume the correct position at the same side of bed. First corpsman places one arm under patient's shoulders, supporting the head on the crook of his arm, the other arm under patient's back. Second corpsman places his arms under patient's back and thighs. Third corpsman places his arms under patient's thighs and calves. At first corpsman's signal, all slide patient to edge of bed. All corpsmen again assume the correct position and at first corpsman's signal, all lift by straightening knees; then turn and place patient on stretcher.

To move the patient from stretcher to bed—use same method (fig. 12-15).

To Move an Injured Arm or Leg

Place pillows in readiness to support extremity. Place both hands beneath the injured limb, at joints above and below the site of injury. Raise limb slowly and gently. Place extremity on pillow, being sure the entire limb is supported. The toes or hands should be slightly higher than the rest of the extremity (fig. 12-16).

Figure 12-15.—To move the patient from bed to stretcher.

Figure 12-16.—To move an injured arm or leg.

DEVICES FOR THE COMFORT OF THE PATIENT

All devices used for the patient's comfort should:

1. Be large enough to support a part along its entire length.
2. Be firm enough to support, yet not cause pressure.
3. Promote correct anatomical alignment (fig. 12-17).
4. Conform to part of body being supported.

10332

Figure 13-8. —Dynamic microphone input.

Figure 13-9. —Carbon microphone input

The microphone input amplifier V1A in figure 13-8 may be connected for use with either a dynamic microphone or a carbon microphone. Connections are normally made at the time of manufacture, but may be changed as a part of a special installation.

When using a dynamic microphone, the amplifier operates as a conventional Class A circuit, and has sufficient gain to increase the level of the microphone, which has relatively small audio output. A balanced input to ground is provided by the primary of transformer T1. The secondary winding of the transformer is connected in parallel with a variable resistor which controls the input signal level at the grid. The output is coupled through C2 to the grid of a second audio amplifier stage, V1B.

When employing a carbon microphone, the circuit arrangement shown in figure 13-9 is used. Tube V1A is then connected as a cathode follower to avoid excessive amplification of the higher level audio provided by the carbon microphone. Since this type of microphone requires a constant current flow, it is connected in series with the 27.5-volt line through current limiting resistor R1, the transformer primary, and ground. The audio signal is developed across variable resistor R2. The output of the stage appears across resistors R3 and R4 and is coupled through C2 to the grid of the following audio amplifier.

An alternate audio input signal employed in the transmitter is supplied by the tone oscillator circuit shown in figure 13-10. The tone generator, V5, supplies a 1,000-cps homing signal when the external tone switch is closed. The action of the switch energizes a tone relay which applies plate voltage to the oscillator and also energizes the transmit-receive relay to place the radio set in the transmit condition.

The tone oscillator is of the phase-shift type with feedback applied to the grid from the

Figure 13-10. —Tone oscillator circuit, ARC-52 transmitter-receiver.

1031 SC01

Figure 12-17.—Position for patient's comfort.

10333

The GATCH BED allows the patient's position to be changed with the least exertion to him. Patients are all different sizes and heights. The breaks in the bed frames for the back and knee rests are in the same place on all beds. Therefore, in most instances, the knee rest will not be usable when the back rest is elevated and vice versa. The knees may be flexed by use of a pillow, rolled sheet, towel, or blanket. The feet should be supported so that they are at right angles to the bed (as in standing position) (fig. 12-18).

WRONG

RIGHT

Figure 12-18.—Proper use of the Gatch bed.

FRACTURE BOARD.—A board the width and length of the mattress used to prevent sagging of the mattress. Used particularly in the care of patients with back injuries or fractures.

BALKAN FRAME.—An overhead apparatus attached to the bed providing a trapeze and attachments for traction. Used for patients who are in casts, in traction, or who are paraplegics.

PILLOWS.—Various sizes may be used, depending upon the purpose. Place pillows in rubber cases when there is a possibility of soiling them. Follow the rules for Devices for Comfort.

FOOTBOARD.—A board the width of the bed and at least 3 inches higher than the patient's toes used to support the feet. The board will help the patient stay in the correct position by preventing his slipping down in bed and will prevent the bedding from pressing on his toes. (fig. 12-19).

Figure 12-19.—Footboard.

AIR RING.—An air ring used to relieve pressure on the coccyx, hips, or on any part of the body. The ring should be inflated just enough to raise the part off the bed. To inflate: Place a paper straw into valve of ring (or cover valve with gauze). Blow up until one-third full of air; close valve (fig. 12-20).

Figure 12-20.—Inflating air ring.

Place ring inside a cotton pillow cover. Place ring under patient so that the part to be protected is directly over the hole of the ring.

Precautions

1. Be sure valve of ring is away from patient's body. For example, between legs when used to relieve pressure on coccyx.

E6E04 0334

2. If ring is too hard after it is under the patient, open valve and release some air so that the ring fits the patient. A hard ring will cause more pressure than no ring at all. A soft ring does not relieve pressure.

3. Rings should be removed every two hours for short periods of time.

Doughnuts (Cotton rings).—Sponge rubber or cotton rings, called doughnuts, may be used to relieve pressure on bony prominences (heels, ankles, elbows, shoulder blades). Where available, sponge rubber cut to fit the part of the supported is recommended (fig. 12-21).

Figure 12-21.—Placement of doughnut.

To make cotton rings: Take cotton wadding of sufficient size to support area. Form into a circle; wind 2 or 3 inch bandage around cotton to make an even, fairly firm ring. Finish bandage with a small piece of adhesive tape.

Cradles.—These are frames of various sizes used to keep weight of bedclothes off patient's leg, toes, or entire body. Anchor cradle to bed by tying to spring or rungs of bed with bandage or string.

Sandbags.—These may be used for support in maintaining certain positions or for immobilization. They are placed also around a part of the body to relieve pain caused by muscle twitching. Cover bag with a pillow case. (Special covers for sandbags may be requested to be made by the linen room.)

Precaution

When using to support an extremity, be sure sandbag is long enough to support entire limb.

DEVICES FOR THE SAFETY OF THE PATIENT

The patient must be protected from injuring himself or, others. The basic safety measure to protect all patients is to have all equipment in good working order. Some patients require additional protection such as side bars, sheet or leather restraints.

SIDE BARS are metal bars, the length of the bed, that serve to keep the patient in bed. Some beds are equipped with bars that slide down when not in use, much like a child's crib. There are detachable bars available for other beds. Side bars are used for patients who are confused, delirious, under sedation, or unconscious. They may also be used as a precautionary measure for patients who are blind or who have had eye surgery.

Sheet Restraints

Tucking in the top bedding along the sides of the bed may provide enough protection for the patient. Sheet restraints may be made by:

1. Folding a sheet in quarters and applying it across the patient's chest and tying it to the bars under the bed. A doctor's order is required. Care must be taken that this restraint does not interfere with the patient's respiration.

2. Folding a sheet diagonally and applying it to the wrist or ankle by means of a clove hitch. A doctor's order is required. Care must be taken that patient's skin does not become chafed (fig. 12-22).

Figure 12-22.—Clove hitch sheet restraint.

Leather Ankle and Wrist Restraints

These restraints MUST have a doctor's order; must be padded; must be loose enough to permit circulation of the parts of the body

10335

restrained; must be placed on opposite sides of the body (right wrist, left ankle); must be slack enough to allow some body movement.

Applying Restraints

1. Pad the wrist or ankle with towel or cotton wadding.
2. Place cuff over pad.
3. Pass strap through loop of cuff and under bar of bed.
4. Allow enough slack in the strap to permit movement.
5. Lock strap.
6. Watch patient for signs of chafing, burning, or pressure sores.

PERSONAL CLEANLINESS OF THE PATIENT

The need for personal cleanliness of a sick person is as great or greater than that for a well person. The care of the skin, mouth and hair follows the same general outline as in your daily life. Good grooming contributes to a sense of well-being, and the absence of it, in most cultures, suggests a low morale. The amount of assistance the patient will need from you in attending to his personal cleanliness will depend upon the amount of activity permitted him by the doctor, and his general and local condition. Most patients prefer to do as much for themselves as possible; others will need to be encouraged to assume their own care.

ORAL HYGIENE

Purpose

To keep mouth clean; refresh patient; to prevent sores and mouth odors; to stimulate appetite. It should be completed:

1. Morning and evening for all patients.
2. Every 1 or 2 hours for patients who have mouth injuries or surgery, have sore inflamed mouths, or are on NOTHING BY MOUTH.
3. Every 2 to 4 hours for patients who have fever, are unconscious, seriously ill, or dying.

Equipment

Glass of water
Curved basin
Toothbrush, dentifrice
Hand towel

Procedure

When Patient is Able to Help Himself

1. Place patient in comfortable position on backrest or on his side.
2. Arrange equipment within his reach on beside or overbed table.
3. Remove equipment promptly when he is finished.

When Patient Needs Some Assistance

1. Turn patient on side.
2. Place towel under his chin and over bedding.
3. Pour water over brush; place dentifrice on brush.
4. Give patient his brush; hold curved basin under his mouth while he brushes teeth.
5. Give water to rinse mouth; take toothbrush.
6. Remove basin; wipe lips and chin with towel.
7. Make patient comfortable.
8. Remove equipment from unit.

When Patient is Unable to Help Himself

1. Add drinking tube to equipment.
2. Proceed as above, doing all steps for patient. Brushing teeth:

Start at front teeth, brush from one side of mouth to the other.

Brush outer surfaces of the upper and lower teeth toward the biting edge.

Do inner surfaces of teeth in same manner.

Use drinking tube to rinse patient's mouth.

SPECIAL MOUTH CARE

Patient requiring special mouth care are the unconscious, dying patient, or one who has had surgery, injuries, or sores of the mouth.

Do not use force to clean wounds, to clean around wires, or to remove crusts.

Equipment

Seven cotton applicators
Mouth wash (1:3 solution)
Glass of water

10336

Tube
Hand towel
Curved basin
Tongue depressor wrapped with gauze bandage
Paper wipes
Bag for waste
Mineral oil
One ounce bulb syringe if patient is unable to use tube.

Procedure

1. Follow instructions as above. Moisten applicators in mouth wash. Use in the same manner as toothbrush.
2. Use new applicator for each section of mouth; discard into bag.
3. Use wrapped tongue depressor for cleansing tongue and holding mouth open.
4. Use drinking tube to rinse mouth. If patient is unable to use tube and is conscious, turn his head to one side and gently irrigate mouth. Direct stream of solution to side of mouth. If patient is unconscious, use moistened applicators.
5. Apply mineral oil to lips and gums.
6. Make patient comfortable, remove equipment.

Care of Equipment

1. Rinse toothbrush under cold running water; replace in patient's bedside table.
2. Discard waste into burnable trash can.
3. Wash metalware with soap and water and replace in patient's bedside locker.
4. Wash glassware with soap and water; boil 10 minutes, dry and stow in proper place; return bulb syringe to CSR for sterilizing.

Charting—Nursing Notes

Time, treatment, any unusual condition noted.

CARE OF DENTURES (FALSE TEETH)

Plates and bridges should be cared for as often and in the same manner as natural teeth.

Equipment

Denture cup for teeth
Toothbrush and dentifrice

Procedure

1. Ask patient to place teeth in denture cup.
2. Take to utility room.
3. Place basin under tap sink and place folded towel or wash cloth in basin as a precautionary measure against breakage.
4. Wash dentures under warm running water over basin.
5. Use patient's brush and dentifrice, rinse dentures well.
6. Put teeth in denture cup; return them to patient.
7. Do not wrap dentures in tissue or towel.

Care of Equipment

Same as for Oral Hygiene

EARLY A. M. CARE

Purpose

The average person in health begins the day refreshed by a night's rest; a sick man, although usually relieved to see the dawn, may be anything but refreshed. Therefore, the purpose of A.M. CARE is to refresh and prepare the patient for breakfast. It should be completed for all bed patients, 1 hour before breakfast, or upon awakening.

Equipment

Face basin, one-half full of hot water.
Glass of water; curved basin
Patient's toothbrush and dentifrice
Hand towel; washcloth
Soap in soap dish
Comb

Procedure

1. Offer bedpan or urinal. Complete this item before continuing.
2. Do oral hygiene
3. Wash face and hands
4. Comb hair
5. Prepare patient for breakfast
   a. In correct position (Fowler's or on side).
   b. Clear top of bedside locker or overbed table for food tray.

For Group of Patients.—Use wheeled cart. Load with equipment as above. Add large

10337
10336

pitcher of hot water, small pitcher of cold water. Distribute equipment to patients who are able to help themselves, then to patients who require help.

EVENING CARE (P.M. CARE)

Purpose

To prepare and relax the patient after the discomforts of the day and to remove or minimize causes of restlessness and sleeplessness during the night. It should be completed for all bed and newly convalescent patients.

Equipment

Same as for A.M. CARE, plus:
1. Rubbing alcohol
2. Powder or skin lotion

Procedure

1. Follow instructions as for A.M. CARE.
2. Add back rub.
3. Straighten and tighten foundation bed, brush out crumbs, and freshen pillows.
4. Bring bedside locker within patient's reach.
5. Give fresh drinking water.
6. Place extra blanket at foot of bed if night is cool.

CLEANSING BATH

The first and perhaps the most important factor for the patient's comfort is the cleanliness of the patient. Cleanliness is essential to the health of anyone, but it is especially so to one who is sick or injured.

Bathing a patient is most important in maintaining his cleanliness, and baths given for that purpose are usually spoken of as cleansing baths. The cleansing bath may be a tub, shower, or bed bath.

Purpose

A cleansing bath is given for the purpose of cleansing the patient in order to observe him; to aid in elimination by keeping the pores of the skin open; to prevent bed sores by stimulating the circulation, and to relax and refresh the patient.

BED BATH

A bed bath is indicated for new patients on admission and daily for all bed patients, preferably in the morning but may be given at any time which best meets the need of the patient.

Equipment

Bath basin or foot tub one-half full of hot water. (110° F.)
Soap in soap dish
Rubbing alcohol, 50 percent, or skin lotion
Nail stick
Nailbrush, if needed
Oral hygiene equipment
Linen as needed: pajamas, bath and hand towels, washcloth

Points to Remember

1. Squeeze washcloth sufficiently to avoid dripping water over bedding.
2. Wrap washcloth around hand and secure ends with thumb or use mitten washcloth, whichever method permits you to squeeze and secure the ends of the cloth and takes the least time (fig. 12-23).

Figure 12-23.—Mitten wash cloth.

3. Expose only that part being bathed.
4. Use long, firm, smooth strokes in bathing.
5. Wash all parts of the body; soak hands and feet.
6. Protect bedding with towel as each part is bathed.
7. Change water after bathing feet and when it becomes dirty, soapy, or cool.
8. Observe patient. Watch for signs of rash, scratching, pressure areas, vermin. Talk to patient during bath; find out how he feels. Any new pains? Aches? Worries?

10338

9. Keep linen off floor. Place soiled linen in hamper.

Procedure

Preparation of patient and his unit is as follows:

1. Screen patient, close windows, and check temperature of ward (7° to 75°F.).
2. Tell patient what you are going to do.
3. Offer bedpan or urinal. Remove before continuing.
4. Gather equipment needed except basin; bring to bedside.
5. Do oral hygiene.
6. Remove oral hygiene equipment; bring in basin of water.
7. Lower backrest; loosen top bedding at foot and sides of bed.
8. Remove pillow; strip and place on chair.
9. Fold spread from top to bottom; pick up in center and place on back of chair.
10. If ward is warm, blanket may be removed in same way.
11. Remove jewelry; place in drawer of bedside stand.

Order of Bath

1. Eyes (no soap)
2. Face, neck, and ears.
3. Far arm, hand, nails.
4. Near arm, hand, nails.
5. Chest
6. Abdomen
7. Far leg, foot, nails.
8. Near leg, foot, nails.
9. Turn patient. Wash sides, back, buttocks; rinse and dry well.
   a. Pour alcohol into hands; then apply evenly to patient's back. Rub until back is dry.
   b. Sprinkle powder or skin lotion into hands; then apply to patient's back. Rub for 5 minutes. Use long, smooth, firm strokes; even pressure; establish definite rhythm; keep hands on back for duration of back rub.
10. Genitals—patient usually prefers to wash himself; corpsman will do so if patient is too ill.

After Bath

1. Put on pajamas.
2. Comb hair.
3. Make up bed. (See occupied bed.)
4. Remove all equipment; leave unit clean and in order.
5. Leave patient comfortable:
   a. In correct position
   b. Call bell, fresh water and bedside table within reach.
6. Clean equipment.

Male patient.—Patient may shave himself either with his a.m. care or before his bath. When corpsman must shave patient, do so before bath or after lunch, before visiting hours.

Female Patient.—Give patient all her makeup equipment after the bed is finished. She will apply makeup while unit is being straightened.

BEDPAN AND URINAL SERVICE

Some patients can be allowed toilet privileges but those who are not must be assisted by the corpsman; the use of the bedpan or urinal is required for many such cases. The bedpan and urinal are utensils into which a patient defecates or voids when he is unable to get out of bed and go to the head. They are devised to protect the patient from unnecessary exertion, exposure, and embarrassment; to prevent soiling of the bed linen; to avoid chilling of the patient, and to assure cleanliness of the patient's body.

Bedpan Service

Purpose

To maintain proper elimination with least exertion to patient.

Equipment

Bedpan
Bedpan cover
Toilet paper

Procedure

1. Screen unit. Take covered bedpan and toilet paper to bedside. (Bedpan may be warmed by running hot water over it and then drying it.)
2. Remove bedpan cover and tuck under mattress on side of the bed.
3. Lift bed covers; remove any air cushions and pillows.

10555

4. Pull pajama coat above waist and pajama pants down to knees.

5. Flex patient's knees; slip one hand under the patient's back, raise his hips, and with the other hand, slip pan into place. Or: Roll patient to side of bed, place the pan against his buttocks, and then roll him back to the center of the bed on the pan.

6. Place toilet paper and bell cord within reach.

7. Leave patient alone unless he is too ill.

8. Answer light immediately when patient calls and remove pan quickly.

9. For patient unable to cleanse himself: Ask patient to turn on his side off the pan; take toilet paper and clean patient.

10. Cover pan and place it on chair.

11. Fix bedding; leave patient in comfortable position.

12. Take pan to utility room; look at contents. Note amount, consistency, color, odor, and unusual appearance (mucus, worms):

a. Normal stool—brown, formed, soft.
b. Blood in stool—black, tarry.
c. Absence of bile in stool—clay-colored gray.

13. Provide patient with basin of water, soap and towel to wash his hands.

14. Care of bedpan:

a Automatic Washer—Place pan in sterilizer, close door, and push flusher valve. Push and hold steam valve for 1 minute. Remove pan and stow in rack or return to patient's unit.

b. Manual Washing—Add cold water to bedpan and empty contents into hopper; clean bedpan with brush and hot soapy water. Boil pan in utensil sterilizer for 20 minutes.

15. Wash your hands.

Urinal Service

Equipment

Urinal and cover.

Procedure

1. Bring covered urinal to patient.

2. Remove urinal promptly after patient has voided.

3. Take urinal to utility room; note color, and appearance. Measure amount and record on DD 792 if required.

4. Clean urinal in same manner as bedpan.

5. Wash your hands.

CARE OF INCONTINENT PATIENT

Purpose

To keep the patient as clean and dry as possible; to prevent decubitus ulcers.

Incontinence may be due to:

1. Loss of muscle tone or paralysis of the anal or urethral sphincter.
2. Urinary retention with overflow.
3. Bedpan or urinal not given when needed.

Procedure

1. Answer patient's calls promptly.

2. Change bedding at once when wet or soiled.

3. Wash patient with soap and water each time he is wet or soiled.

4. Watch for signs of burning, redness, or breaks in the skin.

5. Give frequent back rubs alternating oil and alcohol.

6. Place patient on a bedpan at frequent intervals.

7. Place a urinal for a male patient. Be sure it is level and will not tip over. Empty, clean and replace frequently.

8. Use a large disposable pad or covered rubber sheet under the patient's buttocks.

9. Doctor may order an indwelling catheter to keep the patient dry. See Indwelling Catheter and Simple Drainage.

CARE OF BEDSORES (DECUBITUS ULCER, PRESSURE SORE)

A bedsore is an ulcerated area due to poor circulation to a part of the body as the result of pressure. The presence of bedsores almost invariably denotes lack of care and watchfulness on the part of those responsible for the patient's care. The areas most likely to develop bedsores are the elbows, heels, hips, buttocks, ankles, toes, ears, back of the head, and areas over the end of the spine and shoulder blades (fig. 12-24). All patients confined to bed are susceptible to bedsores. The patients most likely to develop bedsores are incontinent patients, those with lowered vitality

10340

Figure 12-24.—Areas susceptible to bedsores.

due to prolonged illness; the emaciated patients; obese patient; paralyzed patient; unconscious patient, the edematous patient; diabetic, cardiac, or nephritic patients; those with casts, splints, bandages, or in traction.

Causes

1. Constant pressure on an area due to lying in one position too long.
2. Splints, cast, bandages, or traction improperly applied.
3. Moisture due to sweat, urine, feces, water, pus, or other discharges.
4. Friction due to too tight or wrinkled bedding.
5. Pimples or breaks in the skin.
6. Faulty use of the bedpan.

Symptoms

1. Blanching of the skin which quickly turns red when the cause of the pressure is removed.
2. Patient complains of numbness, tingling, or tenderness.
3. Bluish or mottled discoloration of the skin.
4. Breakdown of the skin.
5. Ulceration.

Prevention

1. The most important prevention is the relief of pressure on bony prominences.
2. Inspect the skin of all bed patients every day during the bath and morning and evening care.
3. Change the patient's position every 2 hours.
4. Keep patient and his bed clean and dry.
5. Rub suspected areas frequently, alternate oil and alcohol rubs.
6. Wash, dry and powder patient's skin with talcum or cornstarch each time he is incontinent.
7. Inspect all appliances frequently.

Treatment

1. The best treatment for bedsores is to prevent them.
2. Report any suspicious areas immediately.
3. If skin is broken:
   a. Wash with soap and water; dry well.
   b. Rub the surrounding area with alcohol.
   c. Follow doctor's order for other treatment or medication.

DIETS AND SERVING PROCEDURES

Among the various measures tending to physically support a patient, none perhaps, is of more importance than the food and drink he receives. Illness tends to make a patient very hard to please and notional in regard to food. He may like some things today and tomorrow dislike them, or vice versa. The feeding of a patient must not be taken lightly because food is an important item in his treatment and return to health.

Foods which the patient dislikes, but which have been ordered for him and are essential

for nourishment, may be disguised to alter either taste or appearance. For instance, an egg well beaten may be served in orange juice thoroughly iced, instead of in milk; milk in a cocoa or chocolate shake when the patient does not care for the milk alone; cream in ginger ale rather than as plain cream.

Delay in serving, with food in sight, irritates the patient, sometimes to the point of refusing to eat, and also results in cold food.

The patient's appetite is stimulated by the time of day, by the sight, smell, and taste of food and by the manner and condition in which it is served to him. The ward should be quiet, orderless, and in readiness for meals. No treatment should be done, sick calls made, or visitors permitted during meal hours.

Standard Diets

1. Liquid;
   a. Clear—tea, coffee, broth, gelatines.
   b. Full—add strained soups, juices, ice cream.
2. Soft;
   a. Add chicken, beef; bland vegetables, puddings.
3. Light;
   a. Add light salads, vegetables, lamb, veal, dessert, plain cake.
4. Regular;
   a. Full house diet.
5. Special diets;
   a. For specific conditions, certain foods are increased or decreased according to needs of the patient.

Preparation of Bed Patient

1. Clear bedside stand or overbed table.
2. Bring stand or table within patient's reach.
3. Place patient in sitting position or on his side.
4. Tuck a hand towel under his chin and across his chest.

Preparation of Up Patient

1. Remind patient to be at his bedside when meals are served.
2. Where possible, serve up patients at a table.

Food Trays

At most stations the trays are prepared in the galley or diet kitchen and sent to the wards completely assembled. In these cases the corpsman must ascertain that the patient receives the right tray, the one with his name on it. At stations where food carts are used proceed in the following manner:

1. Wash your hands.
2. Inspect dishes, silverware, and trays for cleanliness.
3. Use clean serving utensils for serving food.
4. Follow Diet List posted in ward diet kitchen.
5. Do not smoke while preparing, setting-up, or serving trays.

Setting-Up Food Trays

1. Sugar, salt, pepper, and water go on most trays, but follow diet lists:
   a. Diabetic diets—omit sugar
   b. Low salt—omit salt
   c. Ulcer diets—omit salt, and pepper
   d. Restricted fluid—omit salt, pepper, water.
   e. Low fat—omit butter.
2. Place cold foods on tray—bread, butter, salad, dessert, milk. Wheel trays and food cart with serving utensils to center of the ward.

Serving Trays

Be sure you have the RIGHT DIET on the RIGHT TRAY for the RIGHT PERSON:

1. Serve small portions; patient may ask for seconds.
2. Place foods in center of dishes; avoid spilling over sides.
3. Fill glasses, cup, and bowls to one-half inch from the top.
4. Place hot foods on each tray as it is served.
5. Cut food into bite size and butter the bread for those patients unable to use knives.
6. Place tray in front of patient so that the knife is on right side of the tray and all dishes are within his reach.

Order of Serving Trays

1. Serve bed patients who are able to feed themselves.

106691

plate through three phase-shifting, RC networks. Each RC section introduces a phase displacement of 60° at a frequency of 1,000 cps, so that a total of 180° phase shift occurs, thereby providing the feedback condition necessary for sustained oscillation. The total phase shift at other frequencies differs from 180° and therefore does not sustain oscillation. The oscillator is designed to operate in the range of 920 to 1,120 cps. The tone output is developed across R12 and fed to the grid of the second audio amplifier, V1B.

Modulator

The modulator supplies the audio energy required to modulate the RF power amplifier of the transmitter. The modulating power is developed by the circuits shown in figure 13-11, the input to which is provided either by the microphone amplifier or by the tone oscillator described in preceding paragraphs.

The signals applied to the audio power amplifiers (fig. 13-11) are referenced to a negative 15-volt bias which is connected to the center tap of the coupling transformer, T3. A Zener diode (CR1) serves to keep the biasing voltage constant during periods of increased modulation when the grids are drawing current. The power tubes are operated push-pull to obtain higher efficiency and linearity of output. The audio output voltage varies about a positive 425 volts, d.c., and is taken from terminal three of T2 for application to the RF power amplifier.

Capacitor C6 (fig. 13-11) is used as a biasing filter. Resistor R11 is used to develop a voltage for monitoring the modulator cathode current and does not affect the normal operation of the circuit.

RF Power Amplifier

The RF power amplifier, the final stage of the transmitter section, applies modulated UHF signals to the antenna at the power level required. Conventional high-level modulation is employed in this stage. A simplified schematic of the power amplifier and associated circuits is shown in figure 13-12.

The input RF to the final stage is applied from the transmitter preamplifier through two

Figure 13-11. —Modulator circuits.

2. Serve up patients.
3. Serve and feed helpless patients.

Feeding the Helpless Patient

1. Place the patient in a sitting position unless otherwise ordered by the doctor.
2. Place a hand towel across the patient's chest; tuck a napkin under his chin.
3. Place tray on overbed table or on bedside stand.
4. Give the patient a piece of buttered bread if he is able to hold it.
5. Feed the patient in the order in which he likes to be fed.
6. Offer fluid during the meal. Use a drinking tube.
7. Do not rush your patient—give a small amount of food at one time; allow patient to chew and swallow food before offering the next spoonful.
8. If patient is inclined to talk, talk with him. It is an excellent time to observe your patient. Find out his likes and dislikes in food, particularly if his appetite is poor or if he is on a special diet.
9. When he is finished, lower backrest; fix his bed so that he may rest.
10. Take tray to diet kitchen; scrape and stack tray.
11. Note amount of food he has eaten; record amount of fluid if on measured intake and output.

Feeding the Blind Patient

1. Follow steps 1, 2, and 3 under Feeding a Helpless Patient.
2. Tell patient what food is on the tray.
3. As you feed him;
   a. Tell him what you are offering him
   b. Whether hot or cold
   c. Whether it is in a spoon, cup, or drinking tube.
   d. Allow him to hold a piece of buttered bread if he wishes.
4. If doctor permits, start patient toward helping himself.
5. Always;
   a. Set tray in the same place in front of him.
   b. Place the dishes in the same order on the tray.
   c. Place the same type of food in the same clockwise position on the dinner plate.
   d. Fill cups and glasses only half full to avoid his spilling fluids.
   e. Go slowly—help him by degrees; a little progress each day will help build his confidence. Stand by until he has confidence in himself.

10348

CHAPTER 13

ADMINISTRATION OF MEDICINES AND THERAPEUTIC TREATMENTS

The administration of medicines is one of the most serious and responsible duties of the corpsman. The corpsman on the ward who is assigned to the task must be thoroughly aware of that responsibility and be absolutely honest and trustworthy. In the administration of medicines the corpsman is expected to:

1. Carry out the doctor's order accurately. Any doubts should be checked with the doctor before giving the medicine, giving the RIGHT DOSE of the RIGHT MEDICINE to the RIGHT PATIENT at the RIGHT TIME and in the RIGHT WAY.

2. To observe, record, and report the effects of the medicine on the patient.

Patients ask corpsmen many questions about drugs prescribed for them. The corpsman should have a clear understanding of what the physician wants the patient to know about the medication used in his treatment. Increasingly, doctors like their patients to be partners in the theraupeutic plan and usually they are frank about the nature and purpose of the drugs they prescribe. The Corpsman should listen with interest to anything the patient may ask or tell him about medication—his mental attitude toward the treatment, the experiences he has had with drugs and particularly any idiosyncrasies to drugs. The latter should be reported at once, but at all times the corpsman should take every opportunity to learn from the patient and he should report what he leans promptly and accurately. On the basis of the corpsman's observations drugs are often discontinued (DC'd) or dosage changed.

Medicines are usually ordered by the doctor for one or all of the following reasons:

1. To promote the patient's health (EXAMPLE: vitamins).

2. To cure the patient's disease (EXAMPLE: antibiotics).

3. To relieve the patient's pain or discomfort (EXAMPLE: narcotics).

SUGGESTED ROUTINE FOR ADMINISTRATION OF MEDICATIONS AND TREATMENTS

Purpose

To provide an orderly, safe and economical method of administering medications and treatments.

RULES FOR ADMINISTRATION OF MEDICATION

Do:

1. Do have an order for medicine signed by the doctor.
2. Do check the patient and his chart before giving each dose of p.r.n. medicine.
3. Do know how to give the drug in the manner prescribed by the doctor.
4. Do wash your hands before preparing the medicine.
5. Do measure all dosages at eye level, whether in a glass or syringe.
6. Do prepare the medicine you give and give the medicine you prepare.
7. Do have a good light when preparing medicine.
8. Do concentrate.
9. Do know how drugs act; whether a local or systemic effect is desired and what possible bad effects might occur.
10. Do know the minimal, average, and maximal dosage of the drugs you give.
11. Do read the label at least three times when preparing a medicine—
    a. When removing from shelf or drawer.

1034[illegible]01

b. Before pouring or preparing it.

c. When returning it to the shelf or drawer.

12. Do give minims when minims are ordered, drops when drops are ordered.

13. Do use surgical aseptic technique in preparing injections and when indicated for instillations and irrigations.

14. Do chart medications after you have given them. Include name, amount, time, and mode of administration, if other than by mouth.

Do Not:

1. Do not give a medicine without an order.
2. Do not allow interruptions while preparing medications.
3. Do not give when doubt exists concerning the patient, the drug or the dose. Consult your doctor or nurse in charge of the ward.
4. Do not use a medicine from an unmarked or poorly labeled bottle or container.
5. Do not return excess medicine to the stock bottle or box; discard into sink.

Equipment

Medication and treatment board. (See fig. 13-1.)

Medication and treatment cards. (See NavMed 6550/4 and NavMed 6550/5.)

The board provides a visible file for all medications and treatments to be given over a 24 hour period. This board should be placed as near to the medicine locker as possible. All boards should provide:

1. Space for 25 hooks. One for each hour and p.r.n.
2. Space between hooks sufficient to allow use of 1 3/4 by 3 inch cards.
3. Instructions on the use of boards and cards.

Medication and Treatment Cards

1. Use NavMed 6550/4 for regularly recurring orders.
2. Use NavMed 6550/5 for p.r.n. orders. Specify frequency at which dose or treatment may be safely repeated.
3. Use NAVMED 1374 for preoperative medications and treatments.

Cards should include all necessary information—patient's name, bed number, medication or treatment, date and hours to be given, discontinuation (DC) date if one is specified, and mode of administration, if other than by mouth.

Figure 13-1.—Medication/Treatment board and card.

Cards must be checked with Doctor's Order Sheets (SF 508) and Nursing Care Plans (Nav-Med 6550/1) at least twice daily—new cards made out for new orders, cards destroyed for discontinued orders. (New order for narcotics should be obtained from the doctor after 48 hours.)

Use of Board and Cards

1. Card is placed on the hook corresponding to the hour the medication or treatment is due.
2. When due, the card is removed, medication or treatment is given, and the card placed on the hook for the hour when it is next due.
3. The medication or treatment is noted in the Nursing notes of the patient's chart.
4. Card of p.r.n. order is placed on hook corresponding to the hour at which it may be safely repeated. Before repeating order, patient and his chart are checked. If order is not needed, the card is moved to the p.r.n. hook.
5. Card of a once daily order is placed face down on the same hook after it has been given.
6. Preoperative medication and treatment cards are not placed on the Medication and Treatment Board. They are attached to the outside front cover of the patient's chart with cellulose tape. At the appropriate time the cards are removed, the medication or treatment is given or completed, charted, and the cards are then destroyed.

MEDICATION BY MOUTH

The corpsman preparing an oral medication should consider how to make the dose acceptable to the patient and precautions to take if the drug has an injurious action on the mouth or teeth.

Drugs are given by mouth in the following forms:

1. Liquids
2. Solids

Administration

1. Shake liquids well before pouring.
2. Dilute liquids with 1/2 ounce of water unless contraindicated.
3. Acids, iron, arsenic, salicylates, iodides, bromides, digitalis, and mercury are given well diluted, through a drinking tube, and usually given after meals so that they may be mixed with the stomach contents which reduces the effect on the stomach walls.
4. For young children or helpless patients, crush pill or tablet and dissolve in small amount of water; use teaspoon instead of medicine glass.
5. Cough medicines are given last, undiluted; instruct patient not to drink any fluids for at least 15 minutes afterwards.
6. Give saline medications for edema in small amounts of water; saline cathartics in large amounts of water.
7. Make disagreeable medicines as palatable as possible.
   a. Castor oil mixed with orange juice and 15 grains sodium bicarbonate.
   b. Add small amount of lemon juice to saline cathartics.
   c. Chill mineral oil; follow with slice of orange.

Equipment

Metal tray with—

1. Medicine cards
2. Medicine dropper
3. Medicine glasses for liquids (disposable if available)
4. Paper cups for pills or tablets
5. Paper straws for drinking tubes
6. Paper wipes
7. Pitcher of water
8. Stirring rod
9. Teaspoons

Procedure

Preparation of Medicines:

1. Wash your hands.
2. Remove cards from board.
3. Arrange cards in sequence similar to placement of patients on ward. Stack cards so that the top card is the only one visible.
4. Take first card; locate and remove medicine from shelf.
5. Read label; compare label with card; place card on tray.
6. Obtain medicine glass; read label; place medicine in glass; place glass on card in tray.
7. Read Label; check medicine card with label on bottle; replace bottle on shelf.
8. Repeat necessary steps 4 through 7 for each remaining card.

Pill, Tablet, Capsule

If in bottle, pour required number into cap or bottle (fig. 13-2).

1031601

If in box, remove required number with spoon.

Powder

In paper—empty into medicine glass, add water, stir with stirring rod.

Measured with a spoon—empty into medicine glass, add water, stir with stirring rod.

Liquid

Shake bottle.

Remove cap. Place cap inside up, on shelf.

Hold medicine glass in one hand so that mark of prescribed amount is at eye level. Place thumbnail at mark (fig. 13-3).

Hold bottle in other hand with label next to palm; pour designated amount.

Wipe rim of bottle with paper wipe; replace cap.

Dilute medicine with 1/2 ounce of water unless contraindicated.

Drops

Use medicine dropper.

Draw up approximate amount of drug from bottle.

Holding dropper at 45 degree angle, count prescribed number of drops into medicine glass (fig. 13-4).

Minims

Use a syringe or a glass graduated in minims.

Follow same procedure as given under liquid.

Administration of Medicines

1. Carry tray to ward.
2. Remove medicine glass and card from tray at same time.

Figure 13-2.—Removing tablets from bottle.

Figure 13-3.—Pouring liquid medication.

3. Identify patient.
   a. Read bed tag.
   b. Check tag with medicine card.
   c. Ask patient his name, compare with card.
   d. Check IDENTO BAND if patient is wearing one and is unable to tell you his name (unconsciousness etc.)
4. Give medicine in glass to patient.
5. Give water with medicine unless contraindicated.
6. Stay with patient until medication has been taken; do not leave medication at bedside.
7. Place medicine glass to one side of tray; turn medicine card face down on tray.
8. Repeat steps 2 through 6 for each remaining medication.

After Medications Have Been Given

1. Chart medications. Return cards to board in correct order (for hour next due).
2. Wash all glasses with hot soapy water; rinse. Boil glasses for 10 minutes.

Figure 13-4.—Correct angle of medicine dropper.

1034701

3. Discard disposable medicine glasses, paper cups etc.
4. Wash spoons, droppers, pitchers and tray.
5. Reset tray.

A wheeled cart may be used for or with a tray; the set up and manner of administration remain the same.

MEDICATION BY SUBLINGUAL ROUTE (UNDER THE TONGUE)

Medicine is in quickly dissolving pill form. The pill is placed under the patient's tongue and allowed to dissolve. NO WATER is given.

MEDICATION BY INHALATION

Medication may be in the form of gases or volatile drugs and given for their local or systemic effect. The inhalation of fumes from volatile drugs is DRY INHALATION. The inhalation of plain steam or steam impregnated with a drug is MOIST INHALATION.

Moist or Steam Inhalations are Used:

1. To relieve inflammation of the mucous membrane in acute colds and sinusitis.
2. To relieve inflammation of the larynx.
3. To soften thick, tenacious mucus and relieve coughing from many causes.
4. To warm and moisten the air following operations such as tracheotomy.

Equipment for Method No. 1

Vaporizer
Medication, if ordered
Water
Bath towel

Precautions

1. Prevent burning the patient. Keep vaporizer 12 to 18 inches away from the patient.
2. Do not wash varporizer under running water; the electrical element must be kept dry.

Procedure

In Utility Room:

1. Fill vaporizer to water level mark.
2. Place medication as directed in instruction for vaporizer.
3. Plug in vaporizer; allow water to boil. Remove plug. Take to bedside.

At Bedside:

1. Bring patient to side of bed.
2. Place bath towel around patient's head.
3. Plug in vaporizer; turn spout so that steam is directed toward the patient.
4. Ask the patient to open his mouth and take deep breaths.
5. Treatments should last 20 minutes.

After Treatment:

1. Dry patient's face.
2. Prevent patient's being chilled. Caution him to stay inside ward for at least 1/2 hour after treatment.

Equipment for Method No. 2

Wash basin
Pitcher
Paper bag
Bath towel
Face towel
Medication
Boiling water

Precautions

Patient must not touch pitcher; ask him to keep his hands at his side.

Procedure

1. Place pitcher in basin.
2. Cut hole in bottom of paper bag to fit over the mouth and nose of the patient.
3. Pour boiling water into pitcher. Place open end of bag over the pitcher.
4. Take to bedside.
5. Have patient place his mouth and nose over hole in the paper bag.
6. Drape bath towel over patient's head and over the pitcher.
7. Ask patient to open his mouth and take deep breaths—about 20 minutes or until water cools.
8. Record date, time, medication, method used, and effect of treatment in Nursing Notes.

MEDICATION BY NEBULIZATION

Purpose

To produce local or systemic effect by application of medication to the respiratory tract.

1034601

By forcing a stream of air over a non-volatile drug in the nebulizer a fine mist or spray is created which contains minute particles of the drug. Such drugs may be administered by using oxygen or hand nebulizer.

Method I

Using oxygen. To be used only when aqueous solutions of medication are to be administered.

Equipment

Oxygen cylinder
Flow regulator
Rubber tubing, 3 feet
Nebulizer
Aqueous solution of medication ordered

Procedure

1. Assemble oxygen cylinder, tubing and regulator as for oxygen therapy. Set flow at 4 to 6 liters.
2. Place drug in nebulizer and connect nebulizer to tubing.
3. Instruct patient to place mouthpiece of nebulizer in mouth and to keep lips closed during the treatment.
4. Treatment lasts approximately 1/2 hour or until all medication is used.

Method II

Using hand nebulizer. To be used when oily solutions of medications are to be administered.

Equipment

Hand nebulizer
Solution ordered

Procedure

1. Place drug in nebulizer.
2. Instruct patient to:
   Place mouthpiece in mouth.
   Inhale with lips closed around mouthpiece.
   Squeeze bulk of nebulizer as he inhales.
   Remove mouthpiece and exhale.
   Repeat procedure until all medication has been used.
   Alternate normal respirations with medicated ones if patient desires.

Methods I and II

Record date, time, medication, method used, and effect of treatment in Nursing Notes.

Wash nebulizer in warm soapy water, rinse and dry after each treatment.

If possible, allow nebulizer to remain in patient's unit until doctor discontinues the order. When order has been discontinued, or nebulizer must be used for other patients, follow the washing by soaking the nebulizer in benzalkonium chloride 1:1000 solution or similar disinfectant.

MEDICATION BY RECTUM

When administration of medicine by mouth is impossible, and when a drug is unpalatable, medication by rectum may be indicated. Ordinarily medication by rectum is for a local effect, but sometimes systemic medication may be given by this route.

Medications may be administered by means of retention enemas or suppositories.

RETENTION ENEMA.—Total quantity of fluid should not exceed 120 cc. (NOTE: Equipment and procedures listed under "enema.")

SUPPOSITORY.—Rectal suppositories are prepared in the shape of a cone. They retain this shape at ordinary room temperatures, but when introduced into the rectum are dissolved by body heat. Drugs contained in them are then released.

Equipment

Prescribed suppository
Finger cot or rubber glove
Lubricant
Toilet tissue

Procedure

1. Explain procedure to the patient.
2. Take equipment to bedside in basin.
3. Screen patient; ask or assist him to turn on his side.
4. Put on glove or finger cot (index finger).
5. Expose rectum.
6. Lubricate glove or cot.
7. Introduce suppository gently into rectum and advance it as far as possible. If patient has difficulty retaining suppository, apply pressure over anus until the desire to defecate has passed.
8. Remove glove; place in basin.
9. A patient should not insert a suppository because it is too difficult for him to do so properly.
10. Record date, time, medication, and effect of treatment in nursing notes.

10343

In Utility Room:

1. Wash and disinfect basin and glove.
2. Discard finger cot.

LOCAL APPLICATIONS OF MEDICATIONS (INUNCTION)

Medication may be applied locally in the form of lotion, ointment or paste. Inunction means to "rub-in" a medication.

APPLICATION OF LOTION

Equipment

Lotion prescribed
Shallow dish
Cotton pledgets

Procedure

1. Pour lotion into shallow dish.
2. Apply lotion to area, using cotton.

APPLICATION OF OINTMENT OR PASTE

Equipment

Ointment or paste prescribed
Tongue blade or spatula
Gauze or soft muslin
Bandage or binder

Procedure

1. With tongue blade, remove ointment from container or squeeze from tube.
2. Spread a thin layer of ointment on gauze.
3. Apply coated gauze to area.
4. Secure with bandage or binder.

NOTE: When applied to wound, sterile articles must be used and aseptic technique maintained.

MEDICATION BY INJECTION

Purpose

To produce rapid systemic effect; to produce local reaction; to administer drugs which are destroyed by gastric juices or those that cannot be taken by mouth.

METHODS OF INJECTION

The method of injection is listed below in order from the least rapid to the most rapid rate of absorption (fig. 13-5).

INTRADERMAL—between the superficial layers of the skin. Used to test for specific allergic reactions.

SUBCUTANEOUS—under the skin into the subcutaneous tissue. Used primarily to administer narcotics and sedatives.

INTRAMUSCULAR—into the muscle. Used when drugs are not suitable for intravenous injection, when a more rapid effect is desired than could be obtained by subcutaneous method, when drug is not readily absorbed, or when it is irritating to subcutaneous tissue.

INTRASPINOUS—into spinal canal. Used primarily for administering anesthetic.

INTRAVENOUS—into the vein. Used when very rapid effects are desired.

The use of individually wrapped autoclaved syringes and needles is required for intravenous and intraspinous injections and is strongly recommended for all injections.

Equipment, Precautions, and Procedures

The following list of equipment, precautions, and procedures apply to all methods of injections (figs. 13-6, 13-7, and 13-8).

General Equipment

Metal tray with—
Individually wrapped autoclaved syringes or autoclaved multiple syringes and needle container.
Sterile covered container of alcohol sponges.
Sterile covered container of 2 X 2's.
Sputum cup without cover for waste.
Thumb forceps in disinfectant solution such as:
Isopropyl alcohol 70 percent, or Benzalkonium chloride 1:1000 aqueous solution, or liquid iodine-type disinfectant, 200ppm available iodine (12cc to 1000 cc water) (anti-rust agent, sodium nitrate, 0.5 percent should be added to these solutions.)

General Precautions

1. Use sterile technique in the preparation and administration of injections.
2. Numbers on the syringe barrel and plunger must be the same.

10350

PREPARATION OF MEDICINES FOR NEEDLE (PARENTERAL) INJECTIONS

MEDICINE FROM STOPPERED VIAL

1. Cleanse stopper with alcohol sponge.
2. Assemble syringe and needle.
3. Draw back plunger of syringe to the amount of solution desired.
4. Insert needle through center of stopper, push in plunger.
5. Invert vial; pull back on plunger, withdraw desired amount; remove needle.
6. Cover needle with alcohol sponge; check point for burrs and hooks.
7. Take to patient.

MEDICINE FROM AMPOUL

1. Wipe file and neck of ampoul with alcohol sponge.
2. File neck of ampoul.
3. Cover ampoul with alcohol sponge.
4. Break off neck of ampoul at file marks.

1. Assemble syringe and needle.
2. Tip ampoul to 45° angle.
3. Insert needle into ampoul, withdraw desired amount of solution.
4. Cover needle with alcohol sponge; check point for burrs and hooks.
5. Take to patient.

ADMINISTRATION OF PARENTERAL MEDICINES

INTRADERMAL

1. Explain to patient.
2. Swab site of injection with an alcohol sponge.
3. Hold syringe upright, expel air bubbles.
4. Insert needle at a 15° angle, just under the skin, so that a raised area is seen.
5. Inject prescribed amount of solution.
6. Cover needle with alcohol sponge, withdraw needle.

SUBCUTANEOUS

1. Explain to patient.
2. Swab site of injection with an alcohol sponge.
3. Hold syringe upright; expel air bubbles.
4. Make a firm cushion of flesh at injection site.
5. Insert needle quickly at a 45° angle.
6. Draw back on plunger; if resistance is felt and no blood seen, slowly inject solution.
7. Place alcohol sponge over needle; quickly remove needle.
8. Gently massage site of injection with alcohol sponge for one minute.

INTRAMUSCULAR

1. Explain to patient.
2. Swab site of injection with an alcohol sponge.
3. Hold syringe upright; expel air bubbles.
4. Make a firm cushion of flesh at injection site.
5. Insert needle quickly at a 90° angle.
6. Draw back on plunger; if resistance is felt and no blood seen, slowly inject solution.
7. Place alcohol sponge over needle; quickly remove needle.
8. Gently massage site of injection with alcohol sponge for one minute.

Figure 13-5.—Preparation and administration of medicine for parenteral injection.

Oc801
10351

Figure 13-6.—Hypodermic tray.

3. Test needle for hooks and burrs before preparing medication (use sterile 2 x 2).
4. Use separation syringe and needle for each injection.

General Procedures

Preparation or Syringe and Needle:

Using individually wrapped autoclaved syringe and needle (recommended method):

1. Open syringe package touching only the outside of the package.
2. Remove plunger and insert into barrel of syringe, touching only the outside of the barrel and the back of the plunger.
3. Pick up needle with tip of assembled syringe.
4. With forceps, gently tighten the needle on the syringe.

Using autoclaved multiple syringe and needle container:

1. Using forceps, remove assembled syringe.
2. Using forceps, remove needle and place on tip of syringe.
3. With forceps, gently tighten needle-on syringe.

Preparation of Solution:

1. Refer to figure 13-5 for preparation of medicine for stoppered vial, ampule, and for tablets readily dissolved (EXAMPLE: codeine).

Figure 13-7.—Syringes for injection.

Figure 13-8.—Needles for injection.

10352

NATIONAL BUREAU OF STANDARDS-1963-A

2. Using tablets readily dissolved—
   a. Place tablet on sterile 2 x 2.
   b. Wipe top of distilled water vial with alcohol sponge; discard sponge.
   c. Remove 1cc of solvent from vial.
   d. Cover needle with alcohol sponge; remove plunger.
   e. Drop tablet into barrel or pick up tablet with the wet tip of the plunger.
   f. Holding the barrel at 45 degree angle, gently insert plunger, avoid dispelling water.
   g. With needle covered by sponge and plunger secured by finger tip, gently agitate syringe until solution is clear.

INTRADERMAL INJECTION

Equipment

26 gauge needle.

Precaution

Be sure the injection is between the layers of the skin. (See figure 13-5 for proper angle of administration.)

SUBCUTANEOUS AND INTRAMUSCULAR INJECTION

Same equipment, precautions, and procedure as under injections. See figure 13-5 for proper administration of parenteral medicines.

INTRAVENOUS INJECTION

The Corpsman is not responsible for intravenous injections of medicine. If in an emergency he is required to do so, the angle of injection is the same as illustrated under figure 13-5 for intradermal injections. DO NOT try it without proper training.

Procedure

1. Prepare solution as directed on package. Use a number 20 or 21 gauge, 2-inch needle.
2. Take prepared syringe and tourniquet to patient.
3. Select site of injection; place tourniquet under arm above elbow; swab site with alcohol sponge.
4. Tighten tourniquet; doctor will insert needle.
5. When blood appears in the syringe, loosen tourniquet.
6. Doctor will inject solution.
7. Place alcohol sponge over needle; doctor removes needle.
8. Apply gentle pressure with alcohol sponge over injection site for a minute.

Care of Equipment

After Each Use:

1. Rinse syringe and needle first with cool water, then detergent, and a final rinse with water.
2. If autoclaved equipment was used, return to Central Supply Room (CSR).
3. Strip entire tray.
4. Return sponge containers to CSR for autoclaving.
5. Send multiple syringe container to CSR for autoclaving.

FRACTIONAL DOSAGE

1. Work out the problem on paper using the formula:

$$\frac{\text{Dose desired}}{\text{Dose on hand}} \times \left(\begin{array}{l}\text{(Quantity of water)}\\ \text{(in minims in)}\\ \text{(which tablet(s))}\\ \text{(are to be dis-)}\\ \text{(solved.)}\end{array}\right) = \begin{array}{l}\text{dose to be}\\ \text{given in}\\ \text{minims.}\end{array}$$

EXAMPLE

If the dose on hand is larger than the dose desired:

Dose desired: Morphine sulfate 1/6 grain.
Dose on hand: Morphine sulfate 1/4 grain.

$$\frac{1/6}{1/4} \times \text{quantity} = \text{amount to be given}$$

1/6 X 4/1 X 24 minims = 16 minims

ANSWER:

Dissolve one (1/4 grain) tablet of morphine sulfate in 24 minims of water. Discard 8 minims—give 16 minims to patient.

EXAMPLE:

If the dose on hand is less than the dose desired it will be necessary to use two or more tablets.

10353

Dose desired: Morphine Sulfate 1/6 grain.
Dose on Hand: Morphine Sulfate 1/8 grain.
Therefore it will be necessary to use 2 tablets.

$$\frac{1/6}{2/8} \text{ X quantity - amount to be given}$$

1/6 X 8/2 X 24 minims = 16 minims

ANSWER:

Dissolve two (1/8 grain) tablets of morphine sulfate in 24 minims of water; discard 8 minims, give 16 minims to the patient.

SPECIAL MEDICINES FOR INJECTION

INSULIN

Types of Insulin

There are three types of insulin now available in the supply catalog:

1. REGULAR or standard insulin in 10 cc vials of three strengths:
   40 units in each cc.; 80 units in each cc. or 100 units in each cc.
2. ISOPHANE insulin (NPH) is available in 10 cc. vials of two strengths:
   40 units in each cc.; 80 units in each cc.
3. PROTAMINE ZINC insulin is available in 10 cc. vials of 40 units in each cc.

Doses of all insulin preparations are measured in UNITS. The strength is indicated by the number of units in each cc of the preparation.

Precaution

All insulins should be stored in the refrigerator (not frozen).

Preparation of Insulin

1. Use a dry, sterile insulin syringe.
2. Use the measure on the syringe corresponding to the strength of the insulin.

EXAMPLE:

Regular insulin U35 has been ordered.

ANSWER:

Locate the U40 scale on the syringe; obtain U40 per cc. strength insulin; withdraw insulin from the vial down to the U35 mark on the U40 scale.

3. Regular insulin should be clear and colorless.
4. Isophane insulin is in suspension and the vials must be gently rotated before use. DO NOT SHAKE VIAL.

PRECAUTIONS

If precipitate has become clumped or has formed a deposit of solid particles on the wall of the vial, return to pharmacy and obtain a new supply.

Administration

1. Check date on vial. DO NOT use beyond expiration date.
2. Give the insulin subcutaneously, at the correct angle of injection. Avoid too deep or too shallow injections.
3. Change the site of injection each time a dose is given. Use both upper arms and anterior thighs in rotation.
4. Time of administration:
   a. Regular insulin—usually 20 minutes before meals.
   b. Isophane—once daily, usually before breakfast.
   c. Protamine zinc—once daily, usually before breakfast.
5. Two types of insulin may be ordered for the patient; ask the doctor if he wishes them to be administered in the same injection. If so, the following method is suggested:

Mixing two types of insulin:

1. Wipe tops of both vials with alcohol sponge.
2. Insert sterile 23 gauge needle into each vial.
3. Without air in the sterile syringe, attach syringe to needle in regular insulin vial.
4. Withdraw prescribed amount of insulin; remove needle and syringe.
5. Remove needle from syringe.
6. Attach syringe to the needle that is inserted into the second vial.
7. Withdraw prescribed amount of insulin; remove syringe and needle from second vial.
8. Gently shake syringe to obtain an even distribution of solution.

GC 10354

PRECAUTION

If either vial of insulin is accidentally mixed with the other type insulin, discard the vial that was accidentally mixed.

MEDICINES IN OILS

1. Warm solution in water bath.
2. Use a large bore needle (20 gauge) to remove solution from the ampule or vial.
3. Most medicine in oil has to be given intramuscularly, using a 20 gauge needle.

ANTIBIOTICS

1. Use autoclaved syringes and needles whenever possible.
2. If syringe has been in alcohol, rinse thoroughly with sterile distilled water before taking up an antibiotic. Alcohol destroys the effectiveness of the antibiotic.

THE ADMINISTRATION OF PARENTERAL FLUIDS

The daily average intake of fluids by a normal adult of average size is about 3,000 cc. This intake consists of the fluid taken as liquids, fluids in solid food, and the water given up as a result of oxidation. The average output of fluid is about the same. This output is that excreted by the kidneys in the form of urine, that lost by the skin through evaporation of air, and fluid lost by the digestive tract in the form of feces. During illness fluids may also be lost through vomitus and hemorrhage.

When a large amount of fluid is lost by the body, it must be replaced. Ordinarily, adequate fluid intake may be maintained by fluids taken by mouth. When a patient is unable to take sufficient fluids by mouth or when his fluid loss has been so great that his intake must be supplemented, fluids are administered by other methods. The doctor may decide to supply fluid by gastric gavage, retention enema, hypodermoclysis, intravenous infusion, or transfusion (fig. 13-9). See procedures relating to Gastrointestinal tract for gavage and retention enema procedures.

The administration of fluids by hypodermoclysis or intravenous methods is the responsibility of the doctor or of the nurse trained by him. The corpsman's role is one of assisting

Figure 13-9.—Types of drip regulators.

with these procedures. In order to do so intelligently he should know:

1. How to prepare his patient and his unit.
2. What and how to prepare necessary equipment.
3. How to assist the doctor.
4. What symptoms or reactions are expected and what danger signs may occur as a result of the treatment.

INTRAVENOUS THERAPY

Intravenous infusion is the term used to designate the giving of fairly large amounts of fluids into the veins. Intravenous injection is the term more often used if the quantity is small and if it is a drug. If blood (and sometimes its

10355

component parts) is given, the injection is called a transfusion. They are given to supply medication and fluids to the body; to increase blood volume; to supply nourishment to the body.

Equipment

Standard (irrigating stand)
Solution ordered
Container of alcohol sponges
Curved basin
Small covered rubber sheet
Technique forceps in container of disinfectant solution
Disposable intravenous set
Correct apparatus for fluid being administered
Arm board
Bandage and scissors
Adhesive tape, 1/2-inch wide cut in 6-inch lengths.
Tourniquet
An airway needle and #18, #19, #20 and #21 gauge 1-1/2 inch needles.

Sites of Injections

1. Median cubital, cephalic or basilic veins
2. Dorsalis pedis vein

Procedure

Preparation of Patient and His Unit:

1. Explain procedure to patient; tell him how he can help.
2. Do any nursing measures required before setting up for intravenous infusion.
3. Offer bedpan or urinal; remove sleeve of gown from arm to be used.
4. Place tourniquet above site of injection. Place arm board under arm, secure with bandage above tourniquet and at wrist.
5. Clear bedside stand of everything except equipment needed.
6. Place standard at foot of bed or fit pole attachment on bed.

NOTE: The use of a board to immobilize the arm during an intravenous infusion is often limited to those patients who are unable to remain quiet during the procedure. The arm of a patient who is to receive an infusion over an extended period of time may be immobilized more comfortably by using a pillow.

Preparation of Solution:

1. Solution should be at room temperature.
2. Hold solution bottle up to the light. Solution should be clear without sediment or shred of mold.
3. Remove cap (see fig. 13-10).
4. Insert 18 G needle into airway vent of bottle. When airway needle is inserted, a rush of air into the bottle should be heard. If this sound is absent, the solution should not be used.
5. Open intravenous administration set and place clamp on tubing. Remove protective rubber cap from tip of drip regulator; insert tip into large depression of rubber stopper of solution bottle. Invert solution bottle; hang on standard.
6. Holding tubing higher than bottle, remove rubber cap from needle adapter—do not touch adapter. Open clamp; slowly lower tubing; allow solution to run through tubing into curved basin until entire tubing is filled with solution

Figure 13-10.—Removing cap of solution bottle.

103356

and all air bubbles are expelled. Attach needle; clamp tubing.

Injection of Fluids

1. Cleanse site of injection with alcohol sponge.
2. Apply tourniquet.
3. Needle is inserted into the vein. When blood appears in tubing, release tourniquet and open clamp on tubing.
4. Regulate flow 40 to 60 drops a minute or at rate ordered by the doctor.
5. Secure needle in place with adhesive. A gauze sponge may be necessary to hold needle at correct angle of injection.
6. Watch for signs of reaction, infiltration.

Care of Patient During Treatment

1. Watch for signs of reaction such as chills or increased pulse rate. Clamp tubing immediately. Notify ward doctor or nurse at once.
2. Keep patient quiet, especially that part of body where needle is inserted. Watch for and report any swelling around needle.
3. Watch the drip regulator and report if fluid stops flowing.

Take pulse frequently; watch color of patient.

Care of Patient After Treatment

1. When solution bottle is almost empty—clamp tubing, remove adhesive, place alcohol sponge over needle, withdraw needle; exert pressure over site of injection until bleeding stops.
2. Straighten patient's clothing and bedding; make patient comfortable.
3. Take all equipment to utility room.

Care of Equipment

1. Discard tubing.
2. Rinse needle with cold water and return to CSR.

WHOLE BLOOD TRANSFUSIONS

The administration of blood must be done with exceptional care since errors may prove fatal to the patient. The preparation of the patient and equipment used is similar to that for administering all other intravenous fluid with the following important exceptions:

1. The plastic set used to administer blood must be a "transfusion set" and contain a filter.
2. An 18 gauge or larger needle should be used to prevent blood from clotting in the needle and obstructing the flow.
3. The patient must have his blood typed and crossmatched with the blood he is to receive. When this is done, the identifying number is placed on the blood transfusion form. It is also placed on the patient's chart. This number must correspond to the number on the bottle of blood to be administered. These identifying numbers must be checked when preparing the patient for the transfusion. They are also checked by the medical officer administering the transfusion as a further precaution against the patient's receiving the wrong blood.
4. Whole blood transfusions are started by the medical officer.

BLOOD TRANSFUSION USING PLASTIC UNIT

The administration of blood and the care of patient follow the same procedures as for "Whole Blood Tranfusions". The preparation of the plastic unit is slightly different; no airway vent is required and a special recipient set is used.

BLOOD TRANSFUSIONS

Observation of the patient during the administration of intravenous fluids and blood.

1. A patient receiving intravenous fluids or blood must be watched very closely during the entire procedure, but particularly during the first 30 minutes that the fluids are running, for any signs of reaction to the fluids. The corpsman should be on the alert for the following:

a. Infiltration of fluid into tissues around the site of injection.

1. This occurs when the needle is dislodged from the vein and the fluids continue to flow into the soft tissue about the vein.
2. Symtoms: Swelling, coldness and blanching of the tissue about the needle injection site, and later cessation of flow of fluids.
3. Action indicated: Clamp off the tubing to stop the flow of fluids; notify the nurse or doctor. If this is detected early, frequently a minor adjustment of the needle into the vein is all that is needed; frequently the needle must be reinserted into another vein.
4. Treatment: If a large amount of fluid has infiltrated into the tissues, the doctor will order compresses and treatments to aid in absorption of this fluid. If the fluid is irritating to the soft tissues sluffing may occur, thus every effort must be made to prevent this.

1035 ... 1032

b. Reaction to the fluids being administered.

1. This occurs when the patient is sensitive to the fluids or blood being administered and is more commonly seen when blood is administered; however, when drugs are added to intravenous fluids the patient may react to these.

2. Symptoms: Restlessness, chills, increased pulse and respiratory rate, spiking temperature, vertigo, cold clammy skin, hives, dyspnea, nausea and vomiting, lumbar pain and cyanosis.

3. Action indicated: Clamp off flow of fluids through tubing immediately, apply external heat in form of extra blankets for chills, notify the doctor immediately, who will administer treatment. Have adrenalin on hand when blood transfusions are being given.

c. Infection

1. This occurs from the administration of contaminated fluids or use of contaminated equipment when giving fluids by vein.

2. Symptoms: Usually delayed but can occur while fluids are being administered if the infecting organism is very virulent. Symptoms are those of septicemia with marked elevation of temperature and pulse rate and prostration of the patient.

3. Action indicated: Prevention is most essential. Inspect fluid for any gross contamination or turbidity; use only sterile equipment and discard needles or tubing if they are contaminated or if contamination is questionable. If symptoms occur while fluids are being administered clamp off the tubing immediately and call the doctor. Send tubing and bottle of fluid to the laboratory for bacteriological studies.

d. Embolism

1. This may occur when air from the tubing is passed into the circulation or when a clot within the circulatory system is carried to a small blood vessel and obstructs it.

2. Symptoms: vary depending on the location of the embolism, usually severe pain in chest, respiratory difficulty and prostration if pulmonary vessels are involved; unconsciousness if cerebral vessel are involved.

3. Action indicated: clamp off tubing and notify doctor immediately; administer oxygen for respiratory difficulty.

Charting—Nursing Notes for Intravenous Infusion or Blood Transfusion

1. Time of start and completion of intravenous infusion or transfusion.
2. Amount, solution and by whom started.
3. Any reaction noted.
4. Signature.

HYPODERMOCLYSIS

Definition

Slow introduction of a large amount of fluid into the subcutaneous tissue.

Purpose

To supply body with fluids; to restore fluid balance; to supply fluids to the body when intravenous infusion is contraindicated or inaccessible.

Equipment

1. Sheet
2. Standard or pole attachment on bed
3. Container of alcohol sponges
4. Technique forceps in container of disinfectant solution
5. Disposable hypodermocylsis set
6. Solution
7. Package of sterile towels
8. One-half inch adhesive tape cut in 6 inch lengths
9. Airway needle; each #19, #20, #21, #22 gauge 1-1/2 or 3 inch needles

Site of Injection

1. Anterior aspect of the thighs (fig. 13-11)
2. Subcutaneous tissue under breasts

Procedure

Preparation of Patient and His Unit:

1. Explain procedure to the patient; tell him how he may help.
2. Do any nursing measures required before setting up hypodermoclysis equipment.
3. Clear top of bedside locker of everything except the equipment needed.
4. Place standard at foot of the bed or fix pole attachment on the bed.

Preparation of Solution:

1. Same as for intravenous infusion.
2. Apply screw clamp to each tube.

10358

3. Attach 21 gauge needle to each tube (keep needles sterile).

Injection of Fluid

1. Fold back bedclothes to below site of injection.
2. Place sheet over patient's body, exposing only area to be used.
3. Cleanse site of injection with alcohol sponges.
4. Fold sterile towel over bedclothes.
5. Needles are inserted into subcutaneous tissues.
6. Open clamps; regulate flow to 40 drops per minute or rate ordered by doctor.
7. Place sterile 4 x 4's under needle hubs; hold in place with adhesive tape.
8. Place sterile towel over field.

Care of Patient During Treatment

1. Watch the site of injection. If area becomes hard, blanched or painful, stop flow until the fluid is absorbed and then restart.

Figure 13-11.—Hypodermoclysis.

2. When solution has been given, clamp tubing; remove needles and cover site of injection with dry sterile dressings.

Care of Patient After Treatment

1. Place patient in a comfortable position, preferably other than the one he has maintained during the treatment.
2. Take all equipment to utility room.

Care of Equipment

1. Discard tubing.
2. Rinse needles with cold water and return to CSR.

Charting—Nursing Notes

1. Time of the start and completion of the hypodermoclysis.
2. Amount, solution, and by whom started.
3. Condition of site of injection on completion of treatment.
4. Any other reactions noted.
5. Signature.

ADMINISTRATION OF OXYGEN

Purpose

To provide an extra supply of oxygen to the patient.

Indicated:

In conditions of anoxia (lack of oxygen) and anoxemia (lack of oxygen in blood). Some symptoms of anoxia are cyanosis and dyspnea, rapid thready pulse and restlessness. Oxygen is used as a supportive measure for patients with cardiac failure, pneumonia, asthma, decompensation, thrombosis, and shock; and is sometimes used for postoperative patients.

SAFETY RULES IN USE OF OXYGEN

In Storerooms

Oxygen cylinders:

1. Keep cylinders secured (strap, chain) in upright position in separate place away from oil, grease, gasoline, matches, alcohol, ether; and from heating equipment such as boilers,

10359

furnaces, radiators, steam pipes, sterilizers or autoclaves.

2. Have storage space well posted with "oxygen—No Smoking" signs.

3. Keep caps on all cylinders.

4. Have separate and clearly marked place for storing full and empty cylinders.

5. Attach DD Form 1191—Warning Tag for Medical Oxygen Equipment—to each cylinder.

6. When removing cylinder from storeroom, remove cap and open and close valve quickly. This is called "cracking the valve" and is done to blow out dirt and debris in the valve. Listen for a hissing sound. Replace cap (fig. 13-12).

Figure 13-12.—Cracking the valve.

Regulators:

1. Store in closed cabinets.

2. Label all regulators with tags "DO NOT OIL OR GREASE."

3. Test regulators frequently for leaks and liter flow accuracy.

4. DO NOT attempt to repair regulators; return regulators to issue room.

Oxygen Tent Machines:

1. Store in cool, clean, dry rooms.

2. Use muslin dust covers to keep apparatus clean.

3. All electrically operated oxygen machines should be grounded. Check with the electrician at your station.

4. Set up and test motor operation at regular intervals every 2 to 3 weeks.

On Ward

1. Post "OXYGEN—NO SMOKING" signs at the entrance to the ward, room or unit.

2. Strap oxygen cylinder to bedpost or to carrier to keep it in an upright position. Cylinder should be placed away from radiators.

3. Instruct all patients and visitors not to smoke within the area.

4. Always have an extra cylinder of oxygen on hand to assure patient a continuous supply. Watch usage rate of oxygen.

EXAMPLES: Full cylinder, at 2,200 pounds pressure, flowing at rate of 6 liters should last approximately 19 hours. A cylinder with 1,000 pounds pressure flowing at a rate of 8 liters per minute should last 6 hours.

5. When an oxygen tent is in operation:

a. Be sure the electrically operating oxygen machine is grounded. Check with the electrician at your station.

b. Do not use electrical devices (call bells, heating pads, vaporizers) inside tent.

c. Do not use alcohol or ether inside tent.

d. Keep patient clothed in cotton material; wool and nylon are dangerous because of their static electrical properties.

6. To attach regulator to cylinder:

a. Remove cylinder valve cap. Insert regulator inlet into cylinder valve outlet and tighten inlet nut with wrench. Before opening cylinder valve, always loosen regulator flow adjusting knob.

b. Open cylinder valve slowly until needle of cylinder gauge stops moving.

c. Turn flow adjusting knob until desired rate of flow shows on flow indicator gauge.

7. To disconnect regulator and cylinder:

a. Close valve tightly.

b. Wait until both cylinder and flow gauges have registered zero.

c. Loosen flow adjusting knob. Unscrew inlet nut. Remove regulator. Recap cylinder.

8. Mark cylinders with the amount of oxygen remaining before returning them to the storeroom.

When Empty:

1. Remove regulator.

2. Close valve; replace cap.

3. Label cylinder "EMPTY." Use shipping tag or piece of adhesive.

Methods of Administration

The method of administering oxygen is selected by the doctor. He may order oxygen to be given through a nasal catheter, by face mask, or by the tent method.

13010360

Mental Preparation of Patient for All Methods

Many individuals associate oxygen therapy with a critically ill patient who is on his death bed. The patient is able to obtain maximum benefit from oxygen only when any fear, anxiety or suspicion is relieved. Present day uses of oxygen therapy onclude supportive and comfort measures as well as therapeutic. Therefore, explain, reassure, and demonstrate what is to be done, how it will relieve him, and what he must do to get the best results.

Nasal Catheter Method

Oxygen by nasal catheter is one of the simplest and most convenient methods of administration. The chief disadvantage is that it may be irritating to the mucous membrane.

Equipment

1. Oxygen cylinder, flow gauge (regulator), humidifier
2. Lubricant (water soluble) and tissue
3. Four feet of rubber tubing
4. Catheter (No. 8 to 14 French) with extra holes along the side and near the tip.
5. Connector (from tubing to catheter)
6. Rubber band and safety pin
7. Wrench (Non-ferrous)
8. Glass of water
9. Adhesive—1 small piece of mark catheter. Two 6-inch strips of 1/2-inch width split half way down.

Procedure

Preparation of Equipment in Utility Room:

1. Open and close valve of oxygen cylinder.
2. Fill humidifier with water to level mark. Attach tubing.
3. Using wrench, attach regulator and humidifier to cylinder.
4. Select largest sized catheter that can be inserted comfortably in patient's nose.
5. Attach catheter to tubing with connector.

Preparation of Patient:

1. Tell patient how and what you are going to do.
2. With the catheter, measure the distance from the tip of the patient's nose to the lobe of his ear; mark this point on the catheter with a small piece of tape. Instruct the patient that he must not breath through his mouth.
3. Turn valve on oxygen cylinder and adjust flow on regulator to 5-6 liters per minutes.
4. Place small amount of lubricant on tissue; pass catheter lightly through the tissue.
5. Hold tip of catheter in glass of water to be sure holes are not plugged.
6. Holding catheter at the taped mark and with the oxygen flowing, insert the catheter into patient's nose slowly up to the taped mark (see fig. 13-13).
7. Ask the patient to open his mouth; the tip of the catheter will be seen opposite the uvula.
8. Tape catheter firmly at tip or side of nose and forehead.
9. Loop elastic band around tubing and pin to bedding, leaving enough tubing to allow patient to move about in bed (see fig. 13-14).

Figure 13-13.—Position of catheter.

Care of Patient with Nasal Catheter:

1. Apply water soluble lubricant about nostril every 4 hours and p.r.n.
2. Give mouth care every 4 hours.
3. Give fluids frequently if permitted.
4. Watch patient; if he shows signs of restlessness, dyspnea, cyanosis, check supply and flow of oxygen and the water level in humidifier. Check opening of catheter.

0361

Figure 13-14.—Taping catheter in place.

5. Always have a clean catheter ready at bedside.

6. Catheter should be changed every 12 hours and more frequently if nasal secretions make it advisable. Use alternate nostrils each change.

Care of Catheters After Use

1. Wash catheters and return to CSR for sterilizing.

Face Mask Method

Equipment

1. Mask
2. Oxygen cylinder and regulator
3. Wrench (non-ferrous)
4. Four feet of rubber tubing and connecting tip
5. Rubber band, safety pin

Procedure

In Utility Room:

1. Open and close valve of oxygen cylinder.
2. Connect regulator, tubing and mask.

At Bedside:

1. Explain what you are going to do to the patient before bringing any equipment to the bedside.
2. Strap cylinder to bed post.
3. Turn on oxygen 6-10 liters per minute.
4. Tell patient what you are going to do.
5. Apply mask to patient's face. Ask him to exhale as it is applied.
6. Adjust the head band so that the mask fits snugly but not too tightly.
7. Reduce liter flow to 6-8 per minute (or rate ordered by doctor) after patient is accustomed to the mask.
8. Loop elastic band around tubing and pin to bed. Be sure tubing is long enough to allow patient to move about in bed.

Care of Patient and Mask:

1. Every 1-1/2 to 2 hours:
   a. Remove mask to sponge and dry patient's face and inside of mask.
   b. Give fluids to drink if permitted.
   c. Reapply mask.
2. Watch rebreathing bag; it should expand when patient exhales and deflate when patient inhales.
3. Oxygen concentration is controlled by liter flow.
   a. For almost 100 percent oxygen concentration adjust liter flow to 6-8 per minute so that bag never fully collapses during inspiration.
   b. For 50-80 percent oxygen concentration, adjust flow to 5-6 liters per minute so that bag collapses during inspiration.
   c. For 40-50 percent oxygen concentration, adjust flow of 4-5 liters per minute so that bag collapses during inspiration.
4. Patient should be comfortable with no dyspnea, cyanosis; pulse should be slower and of better quality.

If he isn't comfortable, check oxygen supply, and check the mask for leakage about nose and mouth. Small piece of gauze or cotton over bridge of nose or on chin may be necessary to prevent leakage.

Care of Mask After Use:

1. Take mask apart.
2. Wash all parts of mask thoroughly with soap and warm water; rinse. Soak in disinfectant 30 minutes. Remove from solution, wash with warm water, rinse.
3. Dry and reassembly mask; return to proper department.

Tent Method

Equipment

1. Tent canopy
2. Oxygen machine

10362

Figure 13-12.—Final amplifier.

amplifiers, V1 and V2. These are grounded-grid circuits and are operated class C. The audio modulating voltage is applied to the plate and screen grid of the final tube. Modulation is accomplished by superimposing the audio voltage upon the RF output of the stage. The resulting modulated RF energy is coupled through capacitor C15 to the antenna relay subassembly. The coupling capacitor is tuned by the mechanical frequency-selection system so that it presents a constant 50-ohm reactance over the entire frequency range of the equipment.

A portion of the modulated output is detected in a sidetone detector circuit, a part of the antenna relay subassembly. The detector circuit contains a crystal diode rectifier, which produces an audible signal to enable the operator to monitor the transmitted signals.

TEST EQUIPMENT

The test equipment used in the maintenance of the ARC-52 is the same as that used with the ARC-27. This is general-purpose type equipment with which you should already be familiar, since it has been in use for a number of years. No special test equipment is needed with ARC-52.

1033

3. Iceless type—does not require ice and has own electrical air conditioning device.
4. Ice type—requires ice (size of a grapefruit) in cooling chamber, pail to catch water from melting ice
5. Oxygen cylinder, regulator
6. Wall thermometer to hang inside tent (for ice type)
7. Hand bell for patient
8. Wrench (non-ferrous)
9. Oxygen analyzer

Procedure

In Utility Room:

1. Check canopy for leaks. Mend with cellutape.
2. Attach canopy to oxygen chamber. Close sleeves of canopy with clips or clothes pins. Close all zippered openings.
3. Fill ice chamber. Iceless type has own temperature control. Empty small drainage drawer on side of cabinet every 24 hours. Check and report any unusual sound in motor.
4. Attach regulator to cylinder (if regulator is part of cabinet, attach to cylinder in patient's room).

At Bedside:

1. Explain what you are going to do to patient before bringing in any equipment.
2. Place rubber sheet between bottom sheet and mattress.
3. Place patient in a comfortable position (Fowler's position preferred).
4. Bring tent and cylinder to the head of the bed. Leave cylinder on carrier or strap cylinder to bedpost away from radiator.
5. Place bath towel around patient's shoulders.
6. Make and check all connections; turn on oxygen to 15 liters a minute. Open shutters in cooling chamber; place pail under drain.
7. Place canopy over upper part of bed, tucking it well under mattress at sides and back. Bring front of canopy down toward foot of bed. Fold cotton sheet in fourths; place front of canopy within folds of sheets and tuck under mattress on both sides.
8. After 20 minutes, or when oxygen analyzer shows correct concentration, reduce oxygen flow to 8 to 10 liters per minute.

Figure 13-15.—Administration of liquids to patients in oxygen tents.

Care of Patient in Tent:

1. Every time tent is opened, oxygen is lost.
2. When giving a bath or changing the bed—draw canopy up to patient's chin; tuck sides under pillows; increase liter flow to 12 to 15 per minute. Use skin lotion for back rubs. Always wash hands before readjusting liter flow after giving a back rub.
3. When giving fluids use tent sleeves rather than opening entire canopy (fig. 13-15).
4. Watch temperature inside tent—maintain at 68 degrees F. Protect patient's head with towel or cap if he complains of cold.
5. Use oxygen analyzer every 4 hours to determine concentration. Follow directions on analyzer.
6. Watch patient carefully; he should be much more comfortable inside tent. If he is not, check:
   a. Oxygen supply, temperature.
   b. Tent for leaks.
   c. Inflow tube or shutter to see that it is not covered by mattress or bedding.
7. The tent is not soundproof; do not discuss patient's condition within his hearing.
8. Be sure he has a hand bell and paper wipes within his reach.

Care of Tent After Use:

1. If disposable type—discard.
2. Other types:
   a. Wash with warm water and soap; rinse with cool water; dry.

1038801

b. Allow to air for 24 hours.
c. Return to proper department.

APPLICATIONS OF HEAT AND COLD

Very frequently applications of heat and cold are a valuable aid in the treatment of patients. Heat causes a local hyperemia (increase blood supply), a function that may be used to advantage in the treatment of inflammation. Also, heat often relaxes the spasm of involuntary muscles, thereby relieving pain. Heat may be applied in the dry or the moist form. Cold is used in the treatment of recent inflammations, because cold contracts the superficial blood vessels, thereby reducing the circulating fluids, and is used for relief of pain caused by pressure. It is also used to control hemorrhage (fig. 13-16).

The applications of heat and cold as described in this section will be limited to those procedures you will be likely to use on the ward or in sick bay. There are many other methods (lamps, diathermy) of applying heat and cold that are administered by the Physical Medicine Department.

The form of application, the temperature at which it is to be applied, and the duration of the application will be prescribed by the doctor.

General Instructions

1. Always have a doctor's order for all applications of heat and cold.
2. Always explain the procedure to the patient.
3. Always screen the patient when applying moist heat or cold.
4. Always wash your hands before starting procedures.
5. Always have a layer of cotton, flannel, or woolen cloth between the patient and any rubber or plastic materials.

EFFECTS OF COLD
Capillaries constrict. Less blood flows to the part. Circulation is lessened. Pain is relieved (anesthetic effect).

NORMAL

EFFECTS OF HEAT
Capillaries dilate. More blood flows to the part. Circulation improves. Pain is relieved. Draining is promoted.

Figure 13-16.—Effects of heat and cold.

10364

6. Always watch the patient's skin closely for signs of redness, mottling, edema, or maceration (softening by soaking).

7. Always chart procedure, noting and recording—

Time of application
Form of application
The area to which it was applied.
The duration of the application.
The name, strength, and temperature of solution (moist applications).
The local or the systemic effects.
Your signature.

APPLICATIONS OF DRY HEAT

Dry heat may be applied to the body by means of a heat cradle, an electric pad, or a hot water bottle. It is used to provide warmth and comfort; to relieve pain; to soothe and relax superficial tissue.

HEAT CRADLE

Heat cradles are frames of various sizes equipped with electric light bulb(s) or heating element to provide warmth to the patients with circulatory disturbances or extensive burns.

Precautions

1. The main precautions to be taken when applying dry heat are to prevent the burning of the patient. For this reason the corpsman should keep the patient under close observation while heat is being applied.
2. Check all electrical connections and wiring before using the cradle.
3. Be sure the cradle is large enough to cover the affected area and to permit the patient to without being burned.
4. Secure the cradle to the bed to prevent it from slipping down over the side and burning the patient.
5. Note the temperature inside the cradle. Those cradles having heating elements are controlled by thermostats. For cradles having electric light bulb(s):

Suspend a wall thermometer inside the cradle.

Control temperature by turning bulb(s) on and off (the usual desired temperature inside the cradle is 90° to 95° degrees F.)

6. Electric light bulb(s) should be 25 watt or less and covered by shields.

ELECTRIC PAD

Precautions

1. Check connections and wiring before using.
2. Keep temperature control on LOW.
3. Do not use with wet applications.

HOT WATER BOTTLE

Equipment

Hot water bottle and cover
Pitcher of water 120° degrees F.

Procedure

1. Test bottle for leaks.
2. Fill bottle one-half full.
3. Place bottle on flat surface, neck up; press from bottom of bottle until water appears in neck of bottle to expel air. Close tightly (fig. 13-17).
4. Wipe dry; again test for leaks; place cover on bottle.
5. Apply bottle to the prescribed area with neck of bottle away from patient's body.

Precautions

1. Always cover bottle.
2. Refill as necessary to keep hot.
3. Observe patient's skin frequently for signs of readness, blistering, and pain.

Figure 13-17.—Filling hot water bottle.

10365

APPLICATIONS OF MOIST HEAT

Moist heat may be applied to the body by means of wet compresses, packs or baths. Irrigations and inhalations are also methods of applying moist heat and are discussed in detail elsewhere in the text. The purposes of applying moist heat are:

1. To relieve inflammation.
2. To provide comfort.
3. To relieve pain.
4. To hasten the localization of infection.

MOIST HOT COMPRESSES (CLEAN)

Purpose

When moist heat is desired for a small area.

Equipment

Tray
Hot plate
Basin of water or solution (105° F.)
Compress of sufficient size to cover area-may be gauze, flannel, or wash cloth
Curved basin
Rubber sheet and cover

Procedure

1. Place compresses in basin of solution on hot plate. Turn on hot plate.
2. Place covered rubber sheet under part to be treated.
3. Wring out excess solution; place compress on part.
4. Repeat step 3 every 1 to 2 minutes for 20 minutes or for prescribed length of time.

Precautions

1. Wring compresses as dry as possible before placing on patient.
2. Observe skin carefully for redness, pain, and blistering.
3. Keep hot plate on LOW after once heated.

STERILE HOT WET COMPRESSES

Used when open lesion or wound is present.

Equipment

Tray
Hot plate
Sterile basin and solution (105° F.)
Sterile compresses
Two sterile forceps
Curved basin
Rubber sheet and cover

Procedure

1. Wash your hands.
2. Place covered rubber sheet under part to be treated.
3. With forceps, place sterile compresses in basin of solution on hot plate.
4. With sterile forceps, wring out excess solution; apply slowly to part.
5. Repeat step 4 every 1 to 2 minutes for 20 minutes.

Precautions

1. Start compresses at low temperature (105° F.) to allow patient to become accustomed to them.
2. Maintain aseptic technique.
3. Watch closely for signs of burning (redness, blisters, pain).
4. Wring out compresses as dry as possible.
5. Keep hot plate on LOW.
6. Use each compress once only.
7. If for both eyes, use separate set-ups for each eye.
8. Wash hands before and after each treatment.

AQUAMATIC K PADS

Equipment

Aquamatic K Pads are electrical units which circulate distilled water at a controlled temperature through a rubber pad. They may be used in application of heat or cold.

Procedure

1. Fill unit with distilled water.
2. Set temperature control.
3. Connect flow tubes from pad to unit.
4. Cover pad and place over part to be treated.

Precautions

1. Tie in place—never use pins.
2. Observe skin frequently for danger signs.

10366

LOCAL PACKS

Local packs are used to provide moist heat to a large area. This is a clean procedure.

Equipment

Cotton flannel or pieces of old, clean blanketing
Rubber or plastic sheeting
Sheet or bath towel for binder
Vaseline or oil for skin
Safety pins or bandage to hold binder in place
Basin of water 110° to 115° F.

Procedure

1. Place flannel or blanketing in basin of water.
2. Place rubber sheet and binder under the part to be treated.
3. Lubricate the skin.
4. Wring out the flannel as dry as possible; apply around part to be treated.
5. Wrap rubber sheet around flannel.
6. Wrap binder around rubber sheet; pin or tie in place.
7. Change wet flannels every half-hour; note the condition of the skin; report signs of puffiness, blisters, wrinkling, paleness of the skin.

Precautions

1. Be sure flannel or blanketing is large enough to cover the area.
2. Be sure flannels are wrung out as dry as possible to avoid burning patients by steam.
3. When applying wet flannel place it gently on the part and momentarily lift the corner to allow the escape of steam.
4. When packs are ordered continuously, expose the area to the air for one-half to one hour daily to help prevent maceration of the skin.
5. Hot water bottles are occasionally used to maintain a constant heat. Place them inside the binder next to the rubber sheet. Be sure they are no hotter than 120° F.
6. When a broken skin area or a wound is present, use sterile water, sterile abdominal pads for dressings; use sterile technique.

HOT WET SOAKS OF ARM OR FOOT

Equipment

Foot-tub one-fourth full of warm water (105° F.)
Pitcher hot water (115° F.)
Rubber sheet and cover
Bath towel

Procedure

1. Place covered rubber sheet under part to be treated
2. Place foot tub on rubber sheet
3. Place part to be treated in tub
4. Pour hot water into tub slowly, away from patient's extremity; stir water as you pour
5. Repeat step 4 as necessary to keep water hot
6. Continue for 20 minutes.

Precautions

1. Pour hot water away from extremity to avoid burning the patient.
2. Have tub on level surface to avoid spilling water.
3. Cover top of tub to hold in heat.
4. Watch skin carefully for signs of burning.

SITZ BATH

Use in treatment of rectal, perineal, or pelvic conditions.

Equipment

Same as for tub bath.

Procedure

Same as for tub bath except—
1. Amount of water should be sufficient to cover patient's hips.
2. Temperature of water should be 110° F.
3. Duration of treatment—20 minutes unless time is specified by doctor.

Caution

If patient shows signs of dizziness, fainting, or exhaustion, stop treatment, drain water from tub, cover patient with blanket. Report to doctor.

APPLICATIONS OF DRY COLD

Dry cold is usually applied to the body by means of an ice bag or ice collar.

Purpose

To check inflammation; to relieve pain; to check bleeding.

10367

ICE BAG

Equipment

Ice bag and cover
Cracked ice (size of walnut)

Procedure

1. Test bag for leaks.
2. Fill bag one-fourth full of ice.
3. Place on flat surface; press from bottom of bag until ice appears in neck of bag, to expel air. Close tightly.
4. Wipe dry; test for leaks; place inside cover.
5. Apply bag to prescribed area with neck of bag away from patient's body.

Precautions

1. Always cover bag.
2. Change cover when it becomes moist.
3. Refill as necessary to keep cold.
4. Observe patient's skin frequently for signs of mottling or pallor, complaint of burning sensation.
5. If patient complains of burning sensation, remove ice bag.

APPLICATION OF MOIST COLD

Moist cold may be applied to the body by means of compresses and baths.

Purpose

To prevent or reduce swelling; to relieve pain; to reduce temperature.

COLD MOIST COMPRESSES (CLEAN)

Equipment

Tray
Basin of ice water (with ice)
Compresses of sufficient size to cover area—may be gauze, flannel or a wash cloth
Curved basin
Rubber sheet and cover

Procedure

1. Place covered rubber sheet under part to be treated.
2. Place compresses in ice water.
3. Wring out excess solution; place compresses on part.
4. Repeat step 3 every 1 or 2 minutes for 20 minutes or for prescribed period of time.

Precautions

1. Watch skin carefully for signs of blanching, mottling.
2. Wring compresses as dry as possible before placing on patient.

COLD MOIST COMPRESSES (STERILE)

Equipment

Tray
Face basin with cracked ice
Sterile solution basin, solution
Two sterile forceps
Sterile compresses (gauze)
Curved basin
Rubber sheet and cover

Procedure

1. Place rubber sheet under part to be treated.
2. With sterile forceps, place sterile compresses in solution basin; then place basin in cracked ice.
3. With sterile forceps, pick up compress; wring out excess solution; apply to part.
4. Repeat step 3 every 1 to 2 minutes for 20 minutes.

BATH—TEPID OR ALCOHOL SPONGE

Purpose

To reduce fever when ordered by the doctor or for patients with fever of 103° F. and above.

Equipment

Bath basin
Seven washcloths or pieces of gauze
Bath and hand towels
Rubber and cotton draw sheets
Hot water bottle and cover
Ice cap and cover
Solution:
Water at 95° to 100° F.
Equal parts water and alcohol at 95° to 100° F.

10368

Procedure

1. Preparation of patient and his unit is the same as for a cleansing bed bath. In addition, place the rubber and cotton draw sheets under him, the ice cap to his head and the hot water bottle to his feet.

2. Order of sponging patient:

Wring out washclothes in solution; place one in each axilla, groin, and under each knee. Replace washcloths frequently.

Follow same order in sponging patient as for Cleansing Bed Bath. Omit genitalia and soaking feet. Pat body dry; avoid vigorous rubbing. Apply alcohol to arms and back.

3. Watch patient for signs of chilliness, cyanosis; increased pulse rate.

Continue treatment for 20 minutes—unless patient shows reaction. In case of reaction, stop sponging; apply blankets and report reaction to ward nurse or doctor.

4. Remake bed; leave patient comfortable. Remove, clean, and store equipment.

5. Take TPR one-half hour after treatment is completed. NOTE: When rapid reduction of very high temperature is desired, bath towels may be substituted for washcloths, thus covering a greater body area with each application. This method must be ordered by the doctor.

PROCEDURES RELATING TO THE GASTROINTESTINAL TRACT

The treatments relating to the gastrointestinal tract are prescribed either to cleanse, to apply heat, to administer or remove fluids, or to administer medication. Most of these treatments require clean equipment and solutions except in the presence of gastric surgery when sterile equipment is needed. All equipment used is these treatments must be sterilized after each use and the returns from these treatments should be discarded down the hopper or bedpan flusher.

INTUBATION

The introduction of tubes through the nose or mouth into the stomach is usually the responsibility of the doctor. However, there are times when a corpsman may be called upon to insert a tube or to teach his patient how to do so.

Purposes:

To obtain a specimen of gastric contents for laboratory examination; to prepare the patient for a gastric lavage, gavage, or siphonage.

Types of Gastric and Intestinal Tubes

LEVIN TUBE (fig. 13-18).—This is a flexible, soft-walled, No. 16 French, 4-foot tube. It has multiple holes near the rounded tip. Markings on the tube indicate distances of 50, 60, 70, 80 centimeters. The Levin tube is used for gastric and intestinal drainage, gastric lavage and gavage. It may be inserted either nasally or orally. It is flexible enough so that there is little danger of producing injury. The chief danger is that the tube may readily enter the trachea.

STOMACH TUBE (Fig. 13-19).—This is a stiff, heavy-walled, No. 28 French, 5-foot tube with a round tip and a funnel at the other end. The stomach tube is used for gastric lavage. It is stiff enough to be easily passed into the stomach of an unconscious or uncooperative patient. The chief danger is that the tube, due to its stiffness, may damage the larynx or

Figure 13-18.—Levin tube.

1036 9301

Figure 13-19.—Stomach tube.

perforate the stomach or esophagus if not carefully used.

CANTOR TUBE (Fig. 13-20).—This is a single lumen, No. 18 French, 10-foot intestinal tube with a small mercury-filled bag at its tip. It is used for intestinal drainage. The tube is inserted nasally, suction is started when the letter "S" on the tube is at the patient's nose.

Figure 13-20.—Cantor tube.

Figure 13-21.—Miller Abbott tube.

MILLER-ABBOTT TUBE (Fig. 13-21).—This is a metal tipped double lumen, No. 16 French, 10-foot intestinal tube with a small balloon near its tip. One lumen of the tube is used to inflate the balloon; the other, entirely independent, for aspiration. Markings on the tube indicate the distance it has been passed. The tube is inserted nasally and suction is started when the first mark is at the patient's nose. Peristaltic action carries the balloon and tube along the intestine.

INTUBATION TECHNIQUE

Equipment

Levin tube in basin of ice water
Water soluble lubricant
20 to 30 cc. syringe
Bath towel
Rubber Sheet
Paper mouth wipes
Curved basin

Procedure

1. Place patient in Fowler's or sitting position. Explain procedure to him.
2. Secure bath towel around his neck. Place rubber sheet over bedding.
3. Remove tube from ice water. Lubricate tip very lightly.
4. Ask patient to tilt head slightly backward.
5. Hold tube about 6 inches from its tip. Rotate it until position of greatest "droop" is found.
6. Holding tube in this position, pass it through the nostril into the pharynx. Ask the patient to tip his head forward and to swallow. Each time he swallows insert the tube a few

10370

10371

inches. Do not use force. Continue inserting the tube until second marker on the tube is reached.

Precaution

Should patient start coughing, choking or become cyanotic, remove the tube quickly. Allow patient to rest a few minutes. Re-insert tube.

7. Attach syringe to tube and aspirate gastric contents.

8. To remove tube:
   Place towel close to patient's chin.
   Pinch the tube at patient's lips.
   Gently but quickly remove tube and place it directly into towel.

Figure 13-22.—Wangensteen apparatus.

GASTRO-INTESTINAL SUCTIONING

Purpose

To provide constant drainage of the gastro-intestinal tract. To relieve or prevent abdominal distention; to remove gas or fluids from gastro-intestinal tract; to relieve intestinal obstruction; to relieve postoperative nausea or vomiting.

Equipment

Levin tube in basin of cracked ice
Lubricant for tube
Adhesive tape strips 1/2" wide x 6" long split halfway down the middle.
Safety pins
Elastic pins
Elastic band
Either (1) electric pump apparatus with drainage bottle, tubing Y connector or (2) hand pump apparatus, drainage bottle with 2 hole stopper and 2 lengths of tubing.

Preparation of Patient and Equipment

1. Screen and tell patient what is to be done. Levin tube is inserted. See intubation technique.

2. If hand pump apparatus is used: (Fig. 13-23)

   a. Connect the two lengths of tubing to the rubber stopper outlets.

   b. Insert rubber stopper into gallon bottle.

   c. Connect the free end of one piece of tubing to the gauge on the tank.

   d. Connect the other piece of tubing to the patient's tube.

   e. To start drainage, open needle valve on tank by turning knurled knob in a counter-clockwise direction.

Figure 13-23.--Hand pump suction apparatus.

10371

f. Create suction to tank by pumping approximately 40 to 50 strokes until the gauge registers 5.

3. If electric (GONCO) pump is used:

a. Connect tube from patient to metal connector located on suction bottle stopper.

b. Turn on water switch to "low".

4. Tape Levin tube to patient's forehead or cheek.

5. Loop elastic band about tubing near connecting tip and pin to bedding.

Care of Patient and Equipment During Treatment

1. Empty and measure contents of the drainage bottle when it becomes two-thirds full or at least every 24 hours.

2. Maintain an accurate intake and output record.

3. Observe working order of the suction apparatus being used and report any interruption in its functioning.

4. Give patient mouth care every 4 hours.

5. Apply ointment or lubricating lotion to each nostril every 4 hours.

6. Do not clamp tubing or stop suction unless ordered by the doctor.

7. Irrigate tube as ordered.

8. Observe patient. Report any complaints of nose or throat irritation; report any sign of blood in drainage.

9. If clear liquids are ordered for the patient by the doctor do not give milk. Do not give solid food.

Care of equipment

1. Wash suction machine.

2. Wash tubing, drainage bottle and cap and return to CSR for sterilization.

3. Return all equipment to proper places.

IMPROVISED (WANGENSTEEN) THREE-BOTTLE METHOD

Equipment

Three gallon bottles

Three lengths rubber tubing—one (6 feet); one (4 feet); one (3 feet) (Fig. 13-24)

Two 2-hole rubber stoppers to fit bottles

Two clamps for tubing

Four lengths glass tubing—one (12 inches); one (6 inches); two (3 inches)

Bandage or tape for hanging bottle

One Levin tube

One connecting tip

One standard or other apparatus for hanging bottle

Procedure

Preparation of Equipment

In Utility Room

Bottles are set up to resemble commercially prepared Wangensteen apparatus (see fig. 13-22).

1. Mark bottles for measuring fluids (see simple drainage).

2. Insert 1 long and 1 short glass tube in each rubber stopper.

Figure 13-24.—Improvised suction apparatus.

1037601

CHAPTER 14

SPECIAL CIRCUITS

BLOCKING OSCILLATOR

The blocking oscillator is another type of relaxation oscillator. It can do many of the things that a multivibrator does. Thus it can be free running, synchronized at each cycle or at a submultiple frequency, or it can be driven in the manner of a one-shot multivibrator.

A blocking oscillator is any oscillator which cuts itself off after one or more cycles because of the accumulation of a negative charge on the grid capacitor. Thus in an oscillator in which the grid swings positive with respect to the cathode, electrons are attracted to the grid and accumulate on the plate of the grid capacitor nearest the grid during charge of the capacitor. Since these electrons cannot return to the cathode through the tube during charge of the capacitor, they must return through the grid-to-cathode resistance. If this resistance is sufficiently large, electrons may accumulate on the capacitor faster than the resistor permits them to return to the cathode. In this case a negative charge is built up at the grid which may bias the tube beyond cutoff. After the tube is cut off, it provides no additional electrons to the grid capacitor. However, the capacitor continues to discharge through the resistor, and a point is reached eventually where the tube again conducts. Thus the process is repeated and the tube becomes an intermittent oscillator. The rate of the recurrence of operating conditions is determined by the RC time constant of the grid circuit.

There are two general types of blocking oscillators—the single-swing type in which the tube is cut off at the completion of one cycle, and the self-pulsing type, in which each cycle of oscillation causes the grid to become progressively more negative until the tube is biased out of operation. In radar the single-swing type oscillator usually operates within the audiofrequency range.

SINGLE-SWING BLOCKING OSCILLATOR

The single-swing oscillator circuit (fig. 14-1) consists of a transformer-coupled oscillator, with a capacitor in series with the grid of the triode V1. For the purpose of understanding its operation, assume that the grid capacitor C_g has been negatively charged by a preceding cycle. The tube, therefore, is biased well below cutoff. As the charge on the capacitor leaks off, the biasing voltage is reduced to the point where the tube begins to conduct. As plate current starts to flow, a magnetic field is set up around the plate winding P of the transformer. The dots at each winding indicate similar polarities. If, for example, a current flows through a winding so that the dot end is positive, the field set up in the core induces voltages in other windings that make the dot end positive in these windings at the same time.

The field builds from zero to a maximum in direct proportion to the plate current, and therefore induces a voltage across the grid winding. This voltage is of such polarity that the grid end goes positive. This action is impressed upon the grid of the tube through the grid capacitor C_g with a polarity that drives the grid more and more positive as the field in the plate winding is building up. When the grid is driven positive with respect to its cathode, it draws current, and electrons accumulate on the plate of the grid capacitor nearest the grid. At the same time, current is flowing through R_g making the grid positive. As the grid becomes more positive, it eventually takes enough electrons from the plate current to lower the rate of the plate current increase. This reduces the induced voltage from plate to grid windings, the grid stops swinging positive, and the plate current increase is slowed. This action is cumulative and ends with the plate current being settled at a constant value,

103601

3. Insert stoppers into 2 bottles.
4. Set up suction apparatus.

Bottle No. 1. Fix bandage, or tape, to hang on hook. Fill to 4,000 cc. with water. Insert stopper with 12 inch glass tubing into bottle. Attach 6-foot length rubber tubing to short glass tube.

Bottle No. 2. Fill with water to 300 cc. Place rubber tubing from bottle No. 1 so that end is under water.

Bottle No. 3. Insert rubber stopper. Attach 4-foot tubing to long tube of bottle No. 1, attach 3-foot tubing to other glass tube.

Apply clamps. One to tubing from bottle No. 1 to No. 3, one to tubing from bottle No. 3 to Levin tube.

At Bedside:

1. Place bottles No. 2 and No. 3 on floor.
2. Be sure all clamps are closed.
3. Invert and hang bottle No. 1 on standard 2 1/2 feet above bed level.

Starting Siphonage:

1. Levin tube is introduced (see intubation technique).
2. Connect Levin tube to tube of drainage bottle No. 3.
3. Release clamp on tubing from bottle No. 1 to No. 3.
4. Release clamp on Levin tube to drainage bottle No. 3. Care of patient is same as for other gastro-intestinal suctioning.

TUBE IRRIGATIONS

Equipment

Basin
Bulb syringle or 30 cc. Luer syringe
Curved basin
Small covered rubber sheet
Solution:
Water or normal saline, 250 to 500 cc. at 100° F.

Precaution

Solution and equipment must be sterile when used for a patient who has had gastric surgery.

Procedure

1. Clamp tubing to drainage bottle.
2. Place covered rubber sheet on bed under connector of Levin tube and drainage tube.
3. Place curved basin under connector.
4. Disconnect tubing.
5. Fill syringe; insert tip into Levin tube; gently inject solution.
6. Allow solution to drain out of tube into curved basin.
7. Repeat steps 5 to 6 until all solution is used.
8. Connect Levin tube to drainage tube; unclamp tube.
9. Remove equipment, measure returned fluid.

Charting—Nursing Notes

Record amount and type of solution used; amount and description of returns.

GASTRIC LAVAGE

Purpose

To empty stomach as a preoperative preparation for gastric surgery; to remove poisons. (requires doctor's order)

Equipment

Tray containing—
Stomach tube in basin of ice water
Two gallon pitchers or warm water (105° F.) or solution ordered by doctor
Large pail for returns
Rubber Sheet and cover
Curved basin; paper wipes

Procedure

Preparation of Patient and His Unit

1. Screen and tell patient what you are going to do.
2. Place patient in Fowler's position.
3. Place covered rubber sheet over bedding and under patient's chin.
4. Give patient curved basin and paper wipes to hold.
5. Place pail on floor or bench at bedside.
6. Locate white marker on stomach tube.

Conducting Lavage

1. Stomach tube is usually inserted by the doctor. The tube is placed far back in the

1037801

mouth and as the patient swallows the tube is advanced a few inches each time until the marker is reached.

2. Invert funnel and hold below the level of the patient's stomach; allow drainage into pail.

3. Hold funnel upright, pour solution into funnel and keep full until approximately 500 cc. has been given.

4. Invert funnel while there is still some solution in it; allow to drain.

5. Repeat steps 3 and 4 until returns are clean or until amount ordered has been used. If patient becomes exhausted, stop lavage; report to doctor.

6. Pinch tube at patient's lips; withdraw quickly into curved basin.

7. Make patient comfortable; remove equipment; leave unit in order.

Care of Equipment

1. Measure returns.
2. Place linen in hamper.
3. Wash tubing, pitcher and basin and return with tray to CSR.
4. Wash pail with soap and water, rubbing vigorously for 2 minutes.

Charting—Nursing Notes

Time of gastric lavage, amount of solution used; amount, appearance and odor of returns. Signature.

NOTE: If Levin tube is used: Tube may be inserted through nose. Add 50 cc syringe to equipment. Plunger of syringe may be used to start or reestablish drainage.

GASTRIC GAVAGE

Purpose

To introduce liquid food or medication into the stomach by means of a tube. When ordered by the doctor for patients who are unable to swallow; who are unconscious; who refuse to eat; who have spasm or stricture of the esophagus.

Equipment

To equipment for intubation technique add:
Fluid to be fed

Procedure

1. Warm liquid food to body temperature.
2. Follow procedure for Intubation Technique, steps 1 through 6.
3. Attach barrel of syringe to tube.
4. Slowly pour fluid down side of syringe. Keep syringe full of fluid until all has been given.
5. Pour 60 cc. of water into tube after fluid to clear tube.
6. To remove tube. Follow step 8 of intubation technique procedure.

Charting—Nursing Notes

Record: Time; amount and name of fluid; state whether tube was introduced orally or nasally. Signature.

ENEMAS

Purpose

To remove feces from lower intestinal tract; to relieve flatulence and abdominal distention; to produce local or systemic effects.

CLEANSING ENEMA

Purpose

To remove feces.

Solution

1. Soap suds solution (S.S.E.) (white soap) 500 to 1,000 cc. Never use philsohex or any detergent.
2. Normal saline solution (N.S.) (1 teaspoon salt to 1 pint of water) 500 to 1,000 cc.
3. Temperature of solution: 105° to 110° F.

Equipment

Tray containing
- Irrigation can
- Rubber tubing
- Clamp
- Glass connecting tip
- Rectal tube No. 24 French
- Lubricant (water soluble)
- Toilet tissue
- Paper towel
- Rubber sheet with cover
- Covered bed pan and urinal

103791

Procedure

Preparation of Patient and Unit

1. Screen patient, explain procedure to him.
2. Clear the top of bedside locker.
3. Lower backrest and turn patient on left side or side most comfortable for him (Sims position). For patients who are paralyzed or unable to retain any fluids, place the patient on a bedpan before injecting fluid.

Preparation of Equipment

1. Attach rectal tube to glass connecting tip; clamp tubing.
2. Fill pitcher with solution—110° F.
3. Pour solution into irrigating can; allow solution to run through tubing; clamp.
4. Remove small amount of lubricant from tube and place on piece of toilet tissue.
5. Lubricate rectal tube; leave tissue around tube.
6. Cover bedpan, place tray on top of pan and carry to bedside. Carry urinal by handle.

Administering Fluid

1. Place bedpan and urinal on chair, tray on bedside table.
2. Fold back upper bedding in triangle to expose anus.
3. Place covered rubber sheet under patient's buttocks.
4. Place curved basin next to anus.
5. Open clamp on tubing, allow small amount of solution to run through tube into curved bedpan.
6. Raise upper buttock, locate anus, insert rectal tube 3 to 4 inches, hold in place with left hand.
7. Open clamp with right hand; hold irrigating can approximately 18 inches above anus (fig. 13-25).
8. Allow solution to flow slowly.
9. If patient complains of discomfort or cramps, pinch tubing for a few moments.
10. Continue flow until patient has taken all solution or as much as he is able.
11. Clamp tubing, pinch and withdraw rectal tube and place in can or tray with rectal tube resting on paper towel.
12. Place patient on bedpan; elevate backrest.
13. Place toilet tissue and call bell within his reach.

Figure 13-25.—Administration of cleansing enema.

14. Carry tray to utility room. Wash your hands.
15. Leave patient alone until he calls, but look in on him frequently.
16. When patient is finished, remove and cover bedpan; assist patient with cleansing if necessary. If patient is unable to expel enema, insert rectal tube and siphon fluid into bedpan.
17. Take bedpan to utility room, inspect contents; note amount, odor, color and consistency, unusual appearance.
18. Take basin of water to patient to wash his hands.

Care of Equipment

1. Rinse irrigating can and tubing with warm water.
2. Run cold water through rectal tube; wash with soap and water; rinse. (Use applicators if necessary to clean "eye" of tube.)

103750 1

3. Return tray to CSR for sterilizing.
4. If no CSR facilities are available then,
   a. Boil irrigating can.
   b. Boil rubber tubing.
   c. After boiling, immerse rubber goods in cold water and dry.
   d. Scour metalware.
   e. Reset tray.
5. Wash rubber sheet with soap and water and dry.

Charting—Nursing Notes

Time
Type of enema given
Results
Reaction of patient
Signature

RETENTION ENEMA

Purpose

To produce a general systemic effect, such as a sedative; to give local remedial effect; to soften feces; to relieve irritation; to relieve flatulence in abnormal distention.

Types

1. Oil enema—4-8 ounces of warm oil (mineral, olive, cottonseed.)

Sedative—drug mixed with 2 to 3 ounces of water, oil, or cornstarch solution. EXAMPLE: chloral hydrate, paraldehyde, sodium bromide, in dosage as ordered by the doctor.

3. Cornstarch—4 to 6 ounces water; dissolve enough starch to make smooth, white fluid. Temperature of solution 100° F.

4. Carminative—1-2-3 enema (one ounces magnesium sulfate, 2 ounces glycerin, 3 ounces water); milk and molasses (6-8 ounces of each) or sodium bicarbonate (8 grams or 2 teaspoonfuls) to 500cc water 105° F.

Equipment

Tray
Pitcher
Funnel
Rectal tube No. 20 French, or catheter
Lubricant
Tongue blade
Toilet tissue
Covered rubber sheet

Procedure

Preparation of Patient and Unit

1. Screen patient; tell him what you are going to do. (A cleansing enema may be ordered 1/2 hour preceding a retention enema to facilitate retention).
2. Clear top of bedside locker.
3. Turn patient on either side (most comfortable position for him).
4. Place covered rubber sheet under patient's buttock.

Preparation of Equipment

1. Prepare solution ordered at correct temperature.
2. Put lubricant on toilet tissue and lubricate rectal tube.
3. Attach rectal tube to funnel. Place in curved basin.
4. Take tray to bedside.

Administration of Fluid

1. Expose anal area by forming triangle of upper bedding. Place curved basin next to anus (fig. 13-26).
2. Fill funnel with solution; allow solution to flow through filling tubing; pinch tubing before funnel is empty.
3. Holding funnel in one hand, raise upper buttock and insert rectal tube about 4 inches.
4. Raise funnel even with top of buttock. Allow solution to flow slowly to avoid stimulating bowel movement. If patient has difficulty retaining solution, apply gentle pressure with toilet tissue to rectum until desire to defecate

Figure 13-26.—Administration of retention enema

10376

has passed. Keep funnel full until all solution has been given.

5. Pinch tube—remove and place in curved basin—disconnect funnel and tube. Place basin on tray.

6. Leave patient on his side; do not disturb him. When giving carminative enema urge patient to retain solution for at least 20 minutes if possible.

7. Take equipment to utility room.

Care of Equipment

Same as cleansing enema.

Charting—Nursing Notes

Record time, type and amount of solution
Whether or not solution was retained
Signature

Disposable Enema Units

Types

1. Cleansing—usually contains hypertonic salt solution which acts by withdrawing fluid from the body by osmosis.

2. Retention (oil)—softens faces and eases passage without straining.

Equipment

1. Squeeze bottle of solution with prelubricated rectal tube.
2. Rubber sheet with cover.
3. Covered bedpan and toilet tissue

Procedure

1. Place patient in left Sim's position.
2. Place covered rubber sheet under patient's buttocks.
3. Remove protective cover from tip of squeeze bottle.
4. Insert tip into anus and gently squeeze bottle.
5. Remove tip and discard disposable unit.
6. Follow procedure for placing patient on bedpan if cleansing enema. Encourage patient to retain if oil retention enema.

COLOSTOMY IRRIGATION

Purpose

To remove faces from the large intenstine.

Equipment

Same as for cleansing enema except—
1. Use smaller tube, Nos. 18 to 22 French Catheter or rectal tube.
2. Normal saline or water, 500 to 750 cc. at 100° F.
3. Add dressing tray and curved basin.
4. Paper bag.

Preparation and Care of Equipment

Same as for a cleansing enema.

Procedure

1. Screen patient; tell him what you are going to do.

2. Turn the patient on the side of his colostomy.

3. Place a covered rubber sheet on the bed under the colostomy.

4. Remove the dressing; place it in the paper bag.

5. Place the second curved basin under the colostomy opening.

6. Introduce lubricated catheter about 4 inches into the colostomy opening, hold the tube in place with the left hand.

7. Raise irrigating can 10 inches above the colostomy.

8. Allow solution to flow slowly until all has been given, then pinch and remove the tube.

9. Leave curved basin in place until return flow stops.

10. Open dressing tray, clean wound with soap solution, apply dressing.

NOTE: Be gentle and tactful with this patient, particularly if the colostomy is a recent one. He has to become accustomed to this new situation in which he has no control of his bowel movements and he has fears of possibly offending and embarrassing himself and others. Reassure and encourage him. The colostomy can be regulated in almost the same way as the rectum but it takes time, patience, attention to diet, and the complete cooperation of the patient and all personnel.

PROCEDURES RELATING TO THE UROGENTIAL TRACT

The treatments relating to the urogenital tract are prescribed in order to cleanse the

10377

Female Patient

Purpose, equipment, and preparation of equipment, same as for male patient. To equipment, add 1 sheet and drop light.

At Bedside

1. Screen patient; tell her what you are going to do.
2. Drape sheet diagonally over patient. Fan-fold bedding to foot of bed.
3. Draping: Fold back corner (2) to groin. Wrap corners (3) and (4) around patient's right and left feet, leaving the genital area exposed (fig. 13-28).
4. Place a covered rubber sheet under patient's buttocks.
5. Place tray on bed between patient's legs, unsterile basin to one side of tray; place drop light to give best light.
6. Open tray, fold back tray cover to patient's buttocks.
7. Put on sterile gloves.
8. Separate labia with left hand.
9. Cleanse labia, urinary meatus, perineum with cotton balls of soap solution. Follow with sterile water. Use each cotton ball once, always wiping from labia to perineum and off. Discard cotton into unsterile basin.
10. Place sterile basin close to buttocks.
11. Pick up catheter, lubricate tip, hold other end of catheter between third and fourth fingers.
12. With other hand separate labia, locate meatus.

Figure 13-27.—Insertion of catheter.

Figure 13-28.—Draping the patient.

13. Insert catheter gently (1 1/2 to 2 inches) until urine begins to flow. Place end of catheter in basin.
14. If specimen is to be obtained, collect about 120 cc. directly into specimen bottle. If urine culture has been ordered, collect specimen in culture tube.
15. Pinch and remove catheter when urine flow stops.
16. Leave patient dry, covered, and comfortable.
17. Clean equipment and return to CSR for sterilization.

BLADDER INSTILLATION

Purpose

To treat the bladder with an antispetic solution.

Equipment

Catheterization tray, plus:
- Medication in sterile container
- Sterile syringe barrel

10379

Procedure

1. Follow procedure for catheterization through removal of urine.
2. Attach syringe to catheter.
3. Pour medication into syringe.
4. When all medication has passed through catheter, pinch and remove catheter.
5. Proceed as in catheterization.

Charting—Nursing Notes

Record: Time; treatment; amount, color, appearance, and odor or urine obtained; complaints of patient—if specimen was obtained. If bladder instillation was performed—state name, strength and amount of solution instilled. Signature.

INDWELLING OR RETENTION CATHETER

The doctor inserts a retention catheter. The corpsman is responsible for the preparation of the patient and equipment and for keeping a record of intake and output.

Purpose

To provide constant drainage of urinary bladder, following surgery when patient is incontinent of urine, or is having difficulty in voiding.

Types of Catheters Used (Fig. 13-29).

MUSHROOM.—The mushroom catheter has a small bulb near the tip. The catheter is stretched over a metal director and inserted. When director is removed, small bulb reforms in bladder, holding catheter in place. This catheter is inserted by the doctor usually in the treatment room or operating room.

Figure 13-29.—(a) Catheter director; (b) Mushroom catheter; (c) Foley catheter; (d) French catheter.

FOLEY.—The Foley catheter is a double lumen catheter; one opening is for drainage, other opening is to small balloon at tip of catheter which is inflated with 4 cc. sterile water after it is inserted into bladder. Screw clamp is then applied to this opening and is not released until catheter is to be removed.

FRENCH.—A French catheter is a straight catheter. It is fastened by placing adhesive tape along one side of the shaft of the penis, wrapped about the catheter, and fastened on the other side of the penis. Two strips of adhesive are then placed around the shaft of the penis in the manner illustrated (fig. 13-30).

Equipment

All equipment for catheterization, plus—

For Foley catheter:
- Sterile catheter
- Sterile solution basin
- Sterile water
- Sterile 10 cc. syringe
- Screw clamp

For Mushroom catheter:
- Sterile catheter
- Sterile metal director
- Sterile drainage tubing and connecting tip
- Gallon drainage bottle
- Rubber band and safety pin
- Adhesive tape
- Bandage

Procedure

1. Follow procedure for Catheterization.
2. Connect catheter to drainage tube (see simple drainage).

BLADDER IRRIGATION

Purpose

To wash out the urinary bladder, to cleanse the area of sediment, bacteria and their products, pus and excess mucus; to relieve inflammation; to control bleeding.

1038

150 OF 327

ED

056 238

MICROCOPY RESOLUTION TEST CHART
NATIONAL BUREAU OF STANDARDS-1963-A

Figure 13-30.—Retention catheter in place.

METHOD I—INTERMITTENT IRRIGATION

Equipment

Catheterization tray
Sterile pitcher
Sterile glass funnel or syringe barrel
250 to 400 cc. sterile solution at 100° F.
Curved basin

Procedure

1. Follow procedure for catheterization through removal of urine.
2. Attach funnel to catheter.
3. Place curved basin under funnel connection.
4. Pour solution slowly along the side of the funnel until 75 to 100 cc. have been given.
5. Invert funnel and allow solution to drain into curved basin.
6. Repeat steps 3 and 4 until all solution has been used.
7. If catheter is to be removed, follow catheterization procedure; if retention catheter is in place, reconnect with drainage tubing.
8. Measure and chart returns of irrigation. Color? Muscus? Pus? Bloody? Cloudy? What was the effect on the patient?

METHOD II—CONTINUOUS IRRIGATION

Equipment

Sterile:
1,000 cc. solution in sterile bottle
Rubber tubing; one 4-foot length, one 2-foot length, and one 1 1/2-foot length.
Connecting tips; one Y tube, one straight tube
Gallon bottle
Two-hole rubber stopper with 2 short pieces of glass tubing
Drip regulator
Airway needle

Unsterile:
Standard
Elastic band, safety pin, and 2 clamps.

Procedure:

Preparation of Equipment

1. Insert two-hole stopper into gallon bottle.
2. Place one clamp on 1 1/2-foot tubing. Close clamp.
3. Insert drip regulator into solution bottle. Attach 4-foot tubing to regulator and to one prong of Y tube (fig. 13-31).
4. Connect 2-foot rubber tubing to drainage bottle and other prong of Y tube.
5. Connect 1 1/2-foot tubing to straight of Y tube.
6. Hang bottle on standard. Release clamp on 4-foot tube. Allow solution to run through tubing until all air is removed. Close clamp.

Irrigating Procedure

1. Explain procedure to the patient.
2. Attach 1 1/2 foot tubing to patient's catheter with straight connecting tip. Open clamp, allow urine to flow into drainage bottle.
3. Loop elastic band around Y tube and pin to patient's drawsheet.
4. Open clamp on 4-foot tubing to permit a flow of 40-60 drops a minute or at a rate ordered by the doctor.

NOTE: For intermittent irrigation—Pinch off outflow tube (2-foot tube), release clamp on inflow tube (4-foot tube), allow 50-100 cc. (doctor's order) to flow into bladder. Close clamp. Release outflow tube. This step is repeated as ordered by the doctor. With the doctor's

1038 1038

Figure 14-1. —Single-swing blocking oscillator.

and the magnetic field of plate winding P becoming stationary with respect to the secondary.

At this time there is no induced voltage in the grid winding and, because there is no charging potential applied, the capacitor begins to discharge. This discharge causes the potential on the grid to become less positive, thereby causing less plate current to flow in the plate winding. The field around the plate coil starts to collapse. This collapsing field, in turn, induces a voltage in the grid winding in the reverse direction, causing the grid to become more and more negative. This process continues until the grid is driven beyond cutoff, thus completing a cycle of operation. Oscillation does not start again immediately, however, because the flow of grid current when the grid was positive has built up enough charge

1075

Figure 13-31.—Bladder irrigation.

permission, the patient may be taught to do it himself.

TIDAL DRAINAGE (MODIFIED LINDSEY)

Purpose

To promote muscle tone in the urinary bladder through the alternate filling and emptying of the bladder.

To remove irritating products of inflammation and urine decomposition by continuous or frequent irrigation.

General Information

The height of the tube assembly as measured above the symphysis pubis of the patient determines the amount of pressure that will be attained within the patient's bladder. If the patient becomes distended or complains of pain before drainage starts, the assembly is too high; if the bladder is being emptied too frequently, the assembly is too low on the standard. When the pressure within the patient's bladder and within the test tube assembly are equal, the small tube will float, causing the syphon to start and the bladder to drain. When the bladder is drained the small test tube comes to rest and the cycle is repeated.

Equipment

All equipment listed for method II of bladder irrigation, plus the following which may be assembled and autoclaved by CSR (fig. 13-32):

- Test tube 13 x 120 mm.
- Test tube 25 x 150 mm.
- L-shaped glass tubing 6-mm. bore
- Straight glass tubing 6-mm. bore
- Two-holed rubber stopper No. 5
- Rubber tubing, 2-foot
- Adhesive

Preparation of Equipment in CSR

1. Cut a groove—1/8 inch wide by 1/8 inch deep—connecting the two holes in the underside of the rubber stopper. (See fig. 13-32).
2. Insert straight glass tubing through stopper for 2 1/2 inches. Insert L glass tubing through stopper so that it is flush with the surface of the stopper.
3. Place small test tube over straight glass tubing.
4. Make a small hole near the base of the large test tube.
5. Insert the stopper assembly into the large test tube. Autoclave.

Preparation of Equipment on Ward

Equipment is assembled the same as for Method II except:

1. Drainage bottle is connected to the straight glass tubing of the Lindsey set.

10382

Figure 13-32.—Tidal drainage (modified lindsey)

Procedure

1. Tape Lindsey set to standard at such a height that the top of the small test tube is about 2 inches above the symphysis pubis of the patient. Clamp tube leading to catheter.

2. Allow solution to flow through tubing until all air is removed. Clamp tube from solution bottle.

3. After patient has been catheterized, attach catheter to tubing. Release clamps; regulate drops at prescribed rate.

4. Compute and record output every 12 hours by subtracting the amount of solution used from the total drainage.

Precautions

1. All connections must be handled without contamination.
2. Solution bottle must be kept filled.
3. Control the speed of inflow by adjusting the screw clamp solution tube.
4. Keep accurate intake and output records.
5. If Kelly flask is used for solution, the top must be kept covered with sterile 4 x 4's.

Charting—Nursing Notes

Time treatment started
Total drainage; amount, name, strength of solution used; patient's output every 12 hours
Description of the returns
Patient's reaction to treatment
Signature

SIMPLE DRAINAGE

Purpose

To provide for removal of fluids from wound or body cavity, when drainage is desired from wound, from urinary bladder, or from other body cavity.

Equipment

Gallon bottle, 2-inch adhesive tape, and ink or colored pencil for marking bottle
Glass connecting tip
Rubber tubing, 3-foot length
Safety pin
Elastic band
Two-inch bandage
Graduate

Procedure

Preparation of equipment

1. Provide for measuring fluid—
Place adhesive tape on side of bottle. Pour 500 cc. water into bottle. Mark water level with ink or colored pencil (fig. 13-33).

10383

Figure 13-33.—Marking the measurement of a bottle.

Continue until 4,000 cc. is reached and marked.

Divide each space between marks evenly with four short lines. Bottle is now graded at 100 cc. levels. Empty bottle.

2. Attach connecting tip to tubing; place other end of tubing in bottle.

Preparation of Patient

1. Attach connecting tip to catheter from wound or bladder.

2. Tie drainage bottle to lower bar of bed at side.

3. Loop rubber band around rubber tubing, pin to bedding. Rubber tubing should be long enough to allow patient to move freely in bed.

During Treatment

1. Watch drainage; check amount, color, appearance, and odor.

2. Empty drainage bottle every 24 hours. Measure and record amount.

Wash bottle with cold water, warm soapy water, rinse and dry.

Care of Equipment

1. Wash and boil equipment.

2. Return equipment to proper place.

10384

CHAPTER 14

CLEANING MEDICAL DEPARTMENT SPACES

Every phase of patient care is important and must be understood by the corpsman. When a patient enters the hospital, he expects treatment for his ailments, and a fast return to normal health. There is nothing more discouraging to the patient or more damaging to the hospital's reputation than to have the patient contract new disease through carelessness or poor sanitary conditions. To avoid spreading disease, the hospital must be kept exceptionally clean. In addition, special cleaning procedures are required for personnel and equipment.

A hospital may be sparkling clean and still spread infections among its patients. Therefore, it is mandatory that the corpsman keep himself and his equipment as aspectic as possible. Remember, hospital facilities are never too clean.

The control of staphylococcal infections is an example of the difficult task confronting the corpsman. Some of these infections do not respond to treatment by the "wonder drugs" and are called ANTIBIOTIC-RESISTANT. This means they are very difficult, and sometimes, impossible to cure. The organisms causing these infections are found everywhere. They survive and multiply in the air, on the body, on equipment, and for that reason extinction is impossible. Control of these infections can be attained through prevention and should be the aim of every person charged with the care of patients. The corpsman can do his part to prevent bacterial growth by careful attention to a scheduled cleaning program.

The cleaning procedures should not disturb the patients more than necessary and should not interfere with their care and treatment, if avoidable. The work required should be assigned on an equal basis. The senior corpsman should remain relatively free of cleaning duties as he must supervise the cleaning and the continuing patient care.

Wards and departments should be kept scrupulously clean at all times and should follow cleaning routines as posted for each. All cleaning should be done using the wet disinfectant technique; dry cleaning is forbidden. This is called good housekeeping.

The following is an example of good cleaning procedures:

1. Medical personnel will continuously observe meticulous aspectic techniques including washing hands and using hexachlorophene soap after care of each patient.

2. Staff personnel will not change from civilian to duty uniforms in patient areas.

3. Particular emphasis on clean clothes, hands, nails, and skin.

4. Staff personnel who acquire a skin or respiratory infection will be relieved of patient care duty until the infection clears.

5. Patients who have skin infections will not be permitted to take tub baths. Showers, using hexachlorophene type soap and water, are considered more effective.

6. When removing dirty linen, handle it gently. Do not inventory soiled linen on ward.

7. Plastic or rubber mattress and pillow covers should be disinfected after each patient use. Blankets should be sent to the laundry after each patient use.

8. Waxed paper bags should be pinned to the patient's bed for disposal of tissues.

9. Bath basins, bed pans and similar equipment should be cleaned with disinfectant and sterilized after use.

10. Treatment carts are not used on wards.

11. Trash and garbage cans are kept covered. They are collected, cleaned, steamed, and returned on a regular schedule.

12. Ward and adjacent spaces and equipment are cleaned on a routine schedule using

10385

a cleaning solution composed of concentrated cleaner diluted with water. To mix the solution, follow instructions on the concentrate container. Using the proper strength of solution, follow the cleaning schedule for the ward. NEVER USE A DRY CLOTH OR SWAB.

a. Decks, lockers, cabinets, counters, shelves, refrigerators, fixtures, air filters, and bedside equipment should be cleaned daily, or more often if necessary.

b. Walls, ceilings, passageways, etc., should be cleaned at least weekly.

c. Treatment and food service items, instruments and utensils, are cleaned and sterilized after each patient use.

d. If a scouring powder must be used, be sure the surface is rinsed clean before allowing to dry.

e. Remember, any procedure that creates or distributes dust will not be used.

f. Areas housing patients with communicable diseases require special precautions for personal and area cleanliness. These precautions should be in addition to the routine procedures, and should be strictly adhered to.

g. Field day is designated to put the extra sparkle to the spaces and should not replace any part of the routine cleaning procedures.

h. Cleaning gear should be properly stowed when not actually in use.

i. The hospital maintenance force will supply clean swabs, cloths, etc., on a daily exchange basis.

SAMPLE CLEANING SCHEDULES

Daily Cleaning

Floors:

1. Sweep down after meals, using sweeping compound. Wet-mop stone, unpolished wooden and linoleum floors.
2. Buff floors each morning.
3. Scrub shower and head floors each a.m. and p.m.
4. Scrub galley floor each a. m. and p. m.

Bedside Units:

1. Damp-dust lockers, beds, chairs, lamps, window sills each a.m.
2. Line up beds, chairs, lockers each a.m., p.m., p.r.n.

Service Rooms:

1. Clean sinks, hoppers, working surfaces each a.m. and p.m.
2. Mop floors each a.m. and p.m.

Weekly Cleaning

Monday:

1. Routine daily cleaning.
2. Damp-dust vents, signal buzzers. Dust electrical fixtures.
3. Clean radiators, electric fans.
4. Clean wheel chairs and special equipment.

Tuesday:

1. Routine daily cleaning.
2. Wash beds, springs, and matresses, chairs, inside and outside of lockers.
3. Polish bright work.

Wednesday:

1. Routine daily cleaning.
2. Dust screens with a brush.
3. Wash windows and venetian blinds.
4. Dust walls with cleaning cloth attached to a long-handled broom.

Thursday:

Field day—any day before inspection.

1. Routine daily cleaning—wax floors. (Exception: orthopedic wards.)
2. Clean medicine lockers, cabinets, desks, cupboards.
3. Wash stretchers, wheel chairs, irrigating stands, screens, overbed tables.
4. Clean gear lockers, racks. Mops should be "twirled and spread out" to dry (in sun if possible). Clean brooms and dust pans.
5. Check all cleaning details.

Friday:

1. Routine daily cleaning.
2. For captain's inspection, open lockers, cabinets, desk drawers. Align beds, chairs, lockers. Open windows evenly; line up venetian blinds or shades.

10386

Saturday and Sunday:

1. Routine daily cleaning.
2. Ward routine and cleaning schedules may be modified in different stations due to local conditions.

SAMPLE ROUTINE FOR INSPECTION

Ward is in order and all patients are present unless excused by ward medical officer.

Ward medical and nurse officers and senior corpsmen stand at entrance to the ward. Other personnel continue with assignments.

Duties of Senior Corpsman:

1. Stand at entrance to ward equipped with a flashlight, ward keys, and hand towel dampened with water at one end.

2. On arrival of the inspection party, call the ward to attention.

3. Precede the inspection party; turn on lights, open doors as the party progresses through the ward.

a. Adjust the pace of the inspection to the desires of the inspecting officer.

b. Offer the dampened towel for the inspecting officer's hands when needed.

c. Be prepared to answer questions concerning the patients and the ward.

d. Be attentive to all suggestions made by the inspecting officer.

e. Escort the inspection party to the exit of the ward.

4. When the inspecting party has left the ward, announce "carry on". Continue with ward routine.

on the grid capacitor to hold the tube cutoff until some of the charge leaks off through the grid resistor.

The time consumed by the rise and decay of plate current depends upon the inductance and resistance of the transformer. The time between pulses depends primarily upon the value of resistance since the grid capacitance is fixed because of pulse-width requirements.

Note the current paths during charge and discharge. The capacitor charges very quickly through the low resistance of the conducting grid-cathode circuit but discharges very slowly through the large grid-leak resistance. The rounded waveshapes show that the voltage and current changes occur more slowly than in a multivibrator. This is due to the inductance in the transformer. The inductance also is the cause of the plate voltage rising above E_{bb} when the tube is cut off. The current continues to flow in the same direction as it charges the distributed capacity in the transformer windings, and causes a voltage drop which adds to E_{bb}. The inductance and distributed capacity form a resonant circuit which tends to oscillate due to shock excitation. If the Q of this LC circuit is high, it may oscillate for several cycles. In the case illustrated (fig. 14-1), damping is at the critical value so that the oscillation occurs for about a half-cycle. Sometimes the plate winding of the transformer is swamped by a resistor to lower the Q, thereby damping oscillations very fast.

The output e_o from this circuit is taken from a third winding on the transformer. However, the output can also be taken from the plate, where a large negative pulse is produced, or from a small resistor in the cathode circuit, where a small but sharp positive pulse is available. The waveshape of the cathode pulse is the same as the plate current waveshape (i_p) shown in figure 14-1.

SYNCHRONIZED BLOCKING OSCILLATOR

The synchronized blocking oscillator shown in figure 14-2 is used as the timing oscillator in a small piece of auxiliary equipment. Normally, the set produces its own PRF independently when the oscillator is free running, as you can see in the waveshapes labeled "eg, no sync." The natural frequency for its operation is about 300 cps. However, synchronizing pulses

Figure 14-2.—Synchronized blocking oscillator.

can be introduced at the plate without making changes in its circuit that may vary the PRF. The synchronization pulses shown occur at 700 cps. Their amplitude is such that one pulse makes the circuit operate, the next pulse does not bring the grid above cutoff, but the

Air Controlman 3 and 2. Rate Training Manual.

Department of the Navy, Washington, D.C.
Bureau of Naval Personnel.
MF AVAILABLE IN VT-ERIC SET.
NAVPERS 10367-D
PUB DATE - 70 343p.

DESCRIPTORS - *MANUALS; VOCATIONAL EDUCATION; *INSTRUCTIONAL MATERIALS; MILITARY PERSONNEL; *MILITARY TRAINING; *AVIATION TECHNOLOGY; RESOURCE MATERIALS; TECHNICAL EDUCATION; *TRADE AND INDUSTRIAL EDUCATION; ADVANCED PLACEMENT PROGRAMS; JOB TRAINING

ABSTRACT - Prepared by the Navy Training Publications Center, this manual is one of a series of training manuals to be used by enlisted personnel studying for advancement in the Air Controlman rating. Information is arranged in 14 chapters which include: (1) Air Controlman Rating, (2) Control Tower Equipment, (3) Aviation Weather Reports and Advisories, (4) Federal Air Regulations, (5) Airport Traffic Control, and (6) Radar and Allied Equipment and Procedures. Also included are definitions and abbreviations, a joint electronics type designation system, an index and a reading list. A related document is available as VT 012 769, also in this issue. (JS)

OFFICE OF EDUCATION
THIS DOCUMENT HAS BEEN REPRODUCED EXACTLY AS RECEIVED FROM THE PERSON OR ORGANIZATION ORIGINATING IT. POINTS OF VIEW OR OPINIONS STATED DO NOT NECESSARILY REPRESENT OFFICIAL OFFICE OF EDUCATION POSITION OR POLICY.

PREFACE

This Rate Training Manual is one of a series of training manuals prepared especially for enlisted personnel of the Navy and Naval Reserve who are studying for advancement in the Air Controlman rating. It may also be used to improve any Air Controlman's daily working proficiency. This manual is based on the professional qualifications for the rates of AC3 and AC2 as set forth in the Manual of Qualifications for Advancement, NavPers 18068 (Series).

This training manual was prepared by the Navy Training Publications Center, Memphis, Tennessee, for the Bureau of Naval Personnel. Technical reviews were provided by the Naval Air Technical Training Center, Glynco, Georgia, the Naval Examining Center, Great Lakes, Illinois, and the Naval Air Systems Command.

THE UNITED STATES NAVY

GUARDIAN OF OUR COUNTRY

The United States Navy is responsible for maintaining control of the sea and is a ready force on watch at home and overseas, capable of strong action to preserve the peace or of instant offensive action to win in war.

It is upon the maintenance of this control that our country's glorious future depends; the United States Navy exists to make it so.

WE SERVE WITH HONOR

Tradition, valor, and victory are the Navy's heritage from the past. To these may be added dedication, discipline, and vigilance as the watchwords of the present and the future.

At home or on distant stations we serve with pride, confident in the respect of our country, our shipmates, and our families.

Our responsibilities sober us; our adversities strengthen us.

Service to God and Country is our special privilege. We serve with honor.

THE FUTURE OF THE NAVY

The Navy will always employ new weapons, new techniques, and greater power to protect and defend the United States on the sea, under the sea, and in the air.

Now and in the future, control of the sea gives the United States her greatest advantage for the maintenance of peace and for victory in war.

Mobility, surprise, dispersal, and offensive power are the keynotes of the new Navy. The roots of the Navy lie in a strong belief in the future, in continued dedication to our tasks, and in reflection on our heritage from the past.

Never have our opportunities and our responsibilities been greater.

C0401 10401

third pulse does make the tube conduct. Since the oscillator is synchronized on alternate pulses, its PRF becomes 700/2, or 350 cps. If the main radar set has a PRF of 1,000 cps and the amplitude of the sync pulses is slightly less than that shown, the blocking oscillator can be synchronized on every third cycle, and it will operate at 333 1/3 cps. By synchronizing this auxiliary set with the big set, indications received by the small set can be displayed on the main indicator, relieving the operator of observing two radar indicators at the same time.

The amplitude of the synchronizing pulse has a great effect on the frequency of this circuit. If the amplitude of the synchronization pulse shown is increased 50 percent, the first pulse that occurs after the circuit begins operation brings the grid above cutoff and the circuit is synchronized on every pulse. As stated before, a low amplitude could cause triggering on every third pulse since the first two will not have sufficient amplitude to make the tube conduct.

In each case, it is assumed that the natural period of the circuit is longer than the time between the pulses which cause the circuit to operate. If the period of the blocking oscillator is shorter, it produces long and short cycles, because the circuit is triggered on some pulses but conducts on its own accord at times.

Maximum frequency stability is achieved in this circuit by connecting the gridload resistor to the plate-voltage supply. This has the same effect as returning the grids to B plus in multivibrators. The useful output from this circuit is taken from a small resistor in the cathode circuit. This resistor has a negligible effect on the operation of the circuit but develops a voltage pulse due to the plate current flowing through it.

Figure 14-3.—Blocked oscillator.

DRIVEN BLOCKING OSCILLATOR

Some electronic circuits require a blocking oscillator which operates only when triggered. Such a circuit might be called a BLOCKED OSCILLATOR since a permanent d-c voltage prevents the circuit from oscillating of its own accord. In the circuit (fig. 14-3), only a positive voltage on the grid or a negative voltage on the cathode can cause the tube to conduct. If the voltage is a pulse, the circuit goes through a cycle of operation, cuts itself off, and the d-c voltage maintains it below cutoff. Cutoff is maintained by a voltage divider from the plate-supply voltage. With the values shown, the cathode voltage is plus 50 volts with respect to ground. The grid is grounded, and is therefore 50 volts negative with respect to the cathode. The grid waveshape shows voltages with respect to the cathode since these are the important voltages in understanding the circuit operation. Cutoff for most tubes used in this type circuit occurs at about minus 18 volts, so the trigger pulse must be more than 50 minus 18, or 32 volts in amplitude to start a cycle of operation. In the grid waveshape

READING LIST

United States Armed Forces Institute (USAFI) courses for additional reading and study are available through your Educational Services Officer.* The following courses are recommended:

C 151 General Mathematics I

E 275 General Science I

*"Members of the United States Armed Forces Reserve components, when on active duty, are eligible to enroll for USAFI courses, services, and materials if the orders calling them to active duty specify a period of 120 days or more, or if they have been on active duty for a period of 120 days or more, regardless of the time specified on the active duty orders."

10403

CHAPTER 1

AIR CONTROLMAN RATING

This training manual is designed to help you meet the professional qualifications for advancement to Air Controlman Third Class and Air Controlman Second Class. The Air Controlman (AC) qualifications which are used as a guide in the preparation of this manual are current through change 3 to the current revision of the Manual of Qualifications for Advancement, NavPers 18068-B. Therefore, subsequent changes in the qualifications may not be reflected in the information given here.

Chapter 1 gives information on the enlisted rating structure, the Air Controlman rating, requirements, and procedures for advancement, and references that will help you in working for advancement and in performing your duties as an Air Controlman.

Chapter 2 presents the military aircraft designation system and general category characteristics to aid the controller in recognizing the variety in aircraft performance with which he must contend when actually controlling air traffic. Chapter 3 points out the importance of flight planning and describes handling procedures for flight plans and related aircraft movement messages. It also includes procedures affecting overdue or missing aircraft, interphone procedure, recording information on flight progress strips, and a brief discussion of NOTAMs, both civil and military. Chapter 4 contains a brief explanation of the Joint Electronics Type Designation System and types of electronic equipment used in most Navy control towers. Chapter 5 discusses basic meteorological elements that affect aviation and chapter 6 shows procedure for encoding and decoding some of the aviation weather reports used by AC's and phraseology for voice transmission of the elements. Chapter 7 deals with basic air navigation including plotting positions, effects of wind, aeronautical chart construction and use, and a use of the E-10 computer. Chapter 8 discusses air navigation aids common to most naval ATC (Air Traffic Control) facilities. Chapter 9 presents the applicable Federal Air Regulations (FAR). Chapter 10 discusses ATC communications including proper format and phraseology, and visual signals. Chapter 11 deals with airport traffic control from basic layout of the airport, through airport markings and lighting, separation of VFR (Visual Flight Rules) air traffic, and emergency recovery equipment ashore. Chapter 12 discusses procedures for controlling IFR (Instrument Flight Rules) air traffic including radar and nonradar separation minimums. Chapter 13 presents radar fundamentals, types of radar equipment used by AC's, and performance characteristics; a basic functional discussion of a RATCC (Radar Air Traffic Control Center) and a CATCC (Carrier Air Traffic Control Center), basic controller procedure and safety precautions concerning electronic equipment. Chapter 14 concerns publications, logs, and records that AC's use and maintain daily to accomplish the facility mission and that regulate the ATC function.

ENLISTED RATING STRUCTURE

The present enlisted rating structure consists of general ratings and service ratings.

General ratings identify broad occupational fields of related duties and functions. Some general ratings include service ratings; others do not. Both Regular Navy and Naval Reserve personnel may hold general ratings.

Service ratings identify subdivisions or specialties within a general rating. Although service ratings can exist at any petty officer level, they are most common at the PO3 and PO2 levels. Both Regular Navy and Naval Reserve personnel may hold service ratings.

10404

AC RATING

The AC rating is a general rating and is included in Navy Occupational Group IX (Aviation). There are no AC service ratings.

Figure 1-1 illustrates the path of advancement from Recruit to Master Chief Air Controlman, Warrant Officer, or Limited Duty Officer. Shaded areas in figure 1-1 indicate career stages from which qualified enlisted men may advance to Warrant Officer (W-1), and selected Commissioned Warrant Officers (W-2 and W-3) may advance to Limited Duty Officer.

The Third and Second Class Air Controlmen perform air traffic control duties in airport control towers, radar air traffic control centers (RATCC's), ground control approach (GCA) units, carrier air traffic control centers (CATCC's), and air operations offices ashore and afloat. They direct aircraft under varying weather conditions by the use of radiotelephone.

To aid in this direction, they employ such devices as radar and direction finding and identification equipment. The Air Controlman assists pilots in the preparation and processing of flight plans and clearances. Maintining current flight planning information is also a responsibility of the Air Controlman.

The Air Controlman must be conscientious and highly motivated in order to effectively perform the duties of his rating. The importance of the Air Controlman rating in the overall mission of the Navy cannot be overemphasized.

As you advance to Air Controlman Third and Second Class, more and more or your worth to the Navy is judged on the basis of the amount of effecient work you are able to obtain from the men under your supervision. The Secretary of the Navy has outlined some of the most important aspects of naval leadership in General Order Number 21.

Naval leadership is the art of accomplishing the Navy's mission through people. It is the sum of those qualities of intellect, of human understanding, and or moral character that enables a man to inspire and to manage a group of people successfully. Effective leadership, therefore, is based on personal example, good management practices, and moral responsibility.

The naval leadership program is a continuing program to develop those qualities of leadership, to the greatest extent possible, in all people within the Naval Establishment.

AC.1

Figure 1-1.—Path of advancement.

ADVANCEMENT

Some of the rewards of advancement are easy to see. You get more pay. Your job assignments become more interesting and more challenging. You are regarded with greater respect by officers and enlisted personnel. You enjoy the satisfaction of getting ahead in your chosen Navy career.

10401

10405

The advantages of advancement are not yours alone. The Navy also profits. Highly trained personnel are essential to the functioning of the Navy. By advancement, you increase your value to the Navy in two ways: First, you become more valuable as a person who can train others and thus make far-reaching contributions to the entire Navy; and second, you become more valuable as a technical specialist in your own rating.

HOW TO QUALIFY FOR ADVANCEMENT

What you must do to qualify for advancement? The requirements may change from time to time, but usually you must:

1. Have a certain amount of time in your present grade.
2. Complete the required Rate Training Manuals by either demonstrating a knowledge of the material in the manual by passing a locally prepared and administered test, or by passing the Enlisted Correspondence Course based on the Rate Training Manual.
3. Demonstrate your ability to perform all the practical requirements for advancement by completing the Record of Practical Factors, NavPers 1414/1.
4. Be recommended by your commanding officer, after the petty officers and officers supervising your work have indicated that they consider you capable of performing the duties of the next higher rate.
5. Successfully complete the applicable military/leadership examination which is required prior to participating in the advancement (professional) examination.

Some of these general requirements may be modified in certain ways. Figure 1-2 gives a more detailed view of the requirements for advancement of active duty personnel; figure 1-3 gives this information for inactive duty personnel.

Remember that the requirements for advancement can change. Check with your educational services office to be sure that you know the most recent requirements.

Advancement is not automatic. After you have met all the requirements, you are eligible for advancement. You will actually be advanced only if you meet all the requirements (including making a high enough score on the written examination) and if quotas permit.

HOW TO PREPARE FOR ADVANCEMENT

What must you do to prepare for advancement? Advancement is not an overnight affair. One does not take the advancement examination and wake up in the morning in the next pay grade. There is a path or sequence of events which one must pursue. Certain things must be done or accomplished before one is admitted to the advancement in rate examination. To prepare for advancement, you will need to be familiar with the "Quals" Manual, the Record of Practical Factors, NavPers 1414/1, Training Publications for Advancement, NavPers 10052 (Series), and applicable Rate Training Manuals. The following sections describe them and give you some practical suggestions on how to use them in studying and preparing for the advancement in rate examination.

"Quals" Manual

The Manual of Qualifications for Advancement, NavPers 18068 (Series), gives the minimum requirements for advancement. This manual is usually called the "Quals" Manual, and the qualifications themselves are often called "quals." The qualifications are of two general types: military requirements, and professional (or technical) qualifications.

Military requirements apply to all ratings rather than to any one particular rating. Military requirements for advancement to third class and second class petty officer rates deal with military conduct, naval organization, military justice, security, watch standing, and other subjects which are required of petty officers in all other ratings.

Professional qualifications are technical or professional requirements that are directly related to the work of each rating.

Both the military requirements and the professional qualifications are divided into subject matter groups; then, within each subject matter group, they are divided into practical factors and knowledge factors. Practical factors are things you must be able to DO. Knowledge factors are things you must KNOW in order to perform the duties of your rate.

The qualifications for advancement and a bibliography of study materials are available in your educational services office. Study these qualifications and the military requirements carefully. The written examination for

10406

ACTIVE DUTY ADVANCEMENT REQUIREMENTS

REQUIREMENTS *	E1 to E2	E2 to E3	#† E3 to E4	# E4 to E5	† E5 to E6	† E6 to E7	† E7 to E8	† E8 to E9
SERVICE	4 mos. service—or completion of recruit training.	6 mos. as E-2.	6 mos. as E-3.	12 mos. as E-4.	24 mos. as E-5.	36 mos. as E-6. 8 years total enlisted service.	36 mos. as E-7. 8 of 11 years total service must be enlisted.	24 mos. as E-8. 10 of 13 years total service must be enlisted.
SCHOOL	Recruit Training.		Class A for PR3, DT3, PT3. AME 3, HM 3			Class B for AGC MUC, MNC.		
PRACTICAL FACTORS	Locally prepared check-offs.	Records of Practical Factors, NavPers 1414/1, must be completed for E-3 and all PO advancements.						
PERFORMANCE TEST			Specified ratings must complete applicable performance tests before taking examinations.					
ENLISTED PERFORMANCE EVALUATION	As used by CO when approving advancement.		Counts toward performance factor credit in advancement multiple.					
EXAMINATIONS**	Locally prepared tests.	See below.	Navy-wide examinations required for all PO advancements.				Navy-wide, selection board.	
NAVY TRAINING COURSE (INCLUDING MILITARY REQUIREMENTS)		Required for E-3 and all PO advancements unless waived because of school completion, but need not be repeated if identical course has already been completed. See NavPers 10052 (current edition).					Correspondence courses and recommended reading. See NavPers 10052 (current edition).	
AUTHORIZATION	Commanding Officer		U.S. Naval Examining Center			Bureau of Naval Personnel		

* All advancements require commanding officer's recommendation.
† 1 year obligated service required for E-5 and E-6; 2 years for E-6, E-7, E-8 and E-9.
\# Military leadership exam required for E-4 and E-5.
** For E-2 to E-3, NAVEXAMCEN exams or locally prepared tests may be used.

Figure 1-2.—Active duty advancement requirements.

10407

INACTIVE DUTY ADVANCEMENT REQUIREMENTS

REQUIREMENTS *	E1 to E2	E2 to E3	E3 to E4	E4 to E5	E5 to E6	E6 to E7	E8	E9
TOTAL TIME IN GRADE	4 mos.	6 mos.	15 mos.	18 mos.	24 mos.	36 mos.	36 mos.	24 mos.

PERFORMANCE TESTS			Specified ratings must complete applicable performance tests before taking examination.					
DRILL PARTICIPATION	Satisfactory participation as a member of a drill unit.							
PRACTICAL FACTORS (INCLUDING MILITARY REQUIREMENTS)	Record of Practical Factors, NavPers 1414/1, must be completed for all advancements.							
NAVY TRAINING COURSE (INCLUDING MILITARY REQUIREMENTS)	Completion of applicable course or courses must be entered in service record.							
EXAMINATION	Standard Exam	Standard Exam or Rating Training.	Standard Exam required for all PO Advancements.			Standard Exam, Selection Board. Also pass Mil. Leadership Exam for E-4 and E-5.		
AUTHORIZATION	Commanding Officer		U.S. Naval Examining Center			Bureau of Naval Personnel		

* Recommendation by commanding officer required for all advancements.

† Active duty periods may be substituted for training duty.

Figure 1-3.—Inactive duty advancement requirements.

0040408

advancement will contain questions relating to the knowledge factors and the knowledge aspects of the practical factors of both the military requirements and the professional qualifications. If you are working for advancement to second class, remember that you may be examined on third class qualifications as well as on second class qualifications.

The "Quals" Manual is kept current by means of changes which occur from time to time. Never trust any set of "quals" until you have checked the change number against an up-to-date copy of the "Quals" Manual. Be sure you have the latest revision.

Record of Practical Factors

Before you can take the Navy-wide examination for advancement, there must be an entry in your service record to show that you have qualified in the practical factors of both the military requirements and the professional qualifications. A special form known as the Record of Practical Factors, NavPers 1414/1, is used to keep a record of your practical factor qualifications. The form lists all practical factors, both military and professional. As you demonstrate your ability to perform each practical factor, appropriate entries are made in the DATE and INITIALS columns.

Changes are made periodically to the Manual of Qualifications for Advancement and revised forms of NavPers 1414/1 are provided when necessary. Extra space is allowed on the Record of Practical Factors for entering additional practical factors as they are published in changes. The Record of Practical Factors also provides space for recording demonstrated proficiency in skills which are within the general scope of the rate but which are not identified as minimum qualifications for advancement.

If you are transferred before you qualify in all practical factors, NavPers 1414/1 should be forwarded with your service record to your next duty station. You can save yourself a lot of trouble by making sure that this form is actually inserted in your service record before you are transferred. If the form is not in your service record, you may be required to start all over again and requalify in the practical factors which have already been checked off.

A second copy of the Record of Practical Factors should be made available to each man in pay grades E-2 through E-8 for his personal record and guidance.

NavPers 10052

Training Publications for Advancement, NavPers 10052 (Series), is a very important publication for anyone preparing for advancement. This bibliography lists required and recommended Rate Training Manuals and other reference material to be used by personnel working for advancement. NavPers 10052 is revised and issued once each year by the Bureau of Naval Personnel. Each revised edition is identified by a letter following the NavPers number. When using this publication, be sure that you have the most recent edition.

If extensive changes in qualifications occur between the annual revisions of NavPers 10052, a supplementary list of study material may be issued in the form of a BuPers Notice. When you are preparing for advancement, check to see whether changes have been made in the qualifications. If changes have been made, see if a BuPers Notice has been issued to supplement NavPers 10052.

The required and recommended references are listed by rate level in NavPers 10052. If you are working for advancement to third class, study the material that is listed for third class. If you are working for advancement to second class, study the material that is listed for second class. Remember that you are also responsible for the references listed at the third class level.

In using NavPers 10052, you will notice that some Rate Training Manuals are marked with an asterisk (*). Any manual marked in this way is MANDATORY—that is, it must be completed at the indicated rate level before you are eligible to take the Navy-wide examination for advancement. Each mandatory manual may be completed by passing the appropriate enlisted correspondence course that is based on the mandatory training manual; passing locally prepared tests based on the information given in the training manual, or in some cases, successfully completing an appropriate Class A school.

Do not overlook the section of Navpers 10052 which lists the required and recommended references relating to the military requirements for advancement. All personnel must complete the mandatory military requirements training manual for the appropriate rate level before they can be eligible to advance.

The references in NavPers 10052 which are recommended, but not mandatory, should also be

80 10409

studied carefully. All references listed in NavPers 10052 may be used as source material for the written examinations at the appropriate rate levels.

Rate Training Manuals

There are two general types of Rate Training Manuals. Rating manuals (such as this one) are prepared for most enlisted rates, giving information that is directly related to the professional qualifications. Basic manuals give information that applies to more than one rate and rating.

Rate Training Manuals are revised from time to time to keep them up to date technically. The revision of a Rate Training Manual is identified by a letter following the NavPers number. You can tell whether any particular copy of a Rate Training Manual is the latest edition by checking the NavPers number and the letter following this number in the most recent edition of List of Training Manuals and Correspondence Courses, NavPers 10061. (NavPers 10061 is actually a catalog that lists current training manuals and correspondence courses; you will find this catalog useful in planning your study program.)

Rate Training Manuals are designed to help you prepare for advancement. The following suggestions may help you to make the best use of this manual and other Navy training publications when you are preparing for advancement.

1. Study the military requirements and the professional qualifications for your rate before you study the training manual, and refer to the "quals" frequently as you study. Remember, you are studying the training manual in order to meet these "quals."

2. Set up a regular study plan. If possible, schedule your study for a time of day when you will not have too many interruptions or distractions.

3. Before you begin to study any part of the training manual intensively, become familiar with the entire manual. Read the preface and the table of contents. Check through the index. Look at the appendixes. Thumb through the manual without any particular plan, looking at the illustrations and reading bits here and there as you see things that interest you.

4. Look at the training manual in more detail, to see how it is organized. Look at the table of contents again. Then, chapter by chapter, read the introduction, the headings, and the subheadings. This will give you a clear picture of the scope and content of the manual. As you look through the manual in this way, ask yourself some questions: What do I need to learn about this? What do I already know about this? How is this information related to information given in other chapters? How is this information related to the qualifications for advancement?

5. When you have a general idea of what is in the training manual and how it is organized, fill in the details by intensive study. In each study period, try to cover a complete unit—it may be a chapter, a section of a chapter, or a subsection. If you know the subject well, or if the material is easy, you can cover quite a lot at one time. Difficult or unfamiliar material will require more study time.

6. In studying any one unit—chapter, section, or subsection—write down the questions that occur to you. Many people find it helpful to make a written outline of the unit as they study, or at least to write down the most important ideas.

7. As you study, relate the information in the training manual to the knowledge you already have. When you read about a process, a skill, or a situation, try to see how this information ties in with your own past experience.

8. When you have finished studying a unit, take time out to see what you have learned. Look back over your notes and questions. Maybe some of your questions have been answered, but perhaps you still have some that are not answered. Without referring to the training manual, write down the main ideas that you have learned from studying this unit. Do not quote the manual. If you cannot give these ideas in in your own words, the chances are that you have not really mastered the information.

9. Use Enlisted Correspondence Courses whenever you can. The correspondence courses are based on Rate Training Manuals or on other appropriate texts. As mentioned before, completion of a mandatory Rate Training Manual can be accomplished by passing an Enlisted Correspondence Course based on the Rate Training Manual. You will probably find it helpful to take other correspondence courses, as well as those based on mandatory training manuals. Taking a correspondence course helps you to master the information given in the training manual, and also helps you see how much you have learned.

10478

10. Think of your future as you study Rate Training Manuals. You are working for advancement to third class or second class right now, but someday you will be working toward higher rates. Anything extra that you can learn now will help you both now and later.

SOURCE OF INFORMATION

One of the most useful things you can learn about a subject is how to find out more about it. No single publication can give you all the information you need to perform the duties of your rating. You should learn where to look for accurate, authoritative, up-to-date information on all subjects related to the military requirements for advancement and the professional qualifications of your rating.

Some of the publications described in this manual are subject to change or revision from time to time—some at regular intervals, others as the need arises. When using any publication that is subject to change or revision, be sure that you have the latest edition. When using any publication that is kept current by means of changes, be sure you have a copy in which all official changes have been made. Studying canceled or obsolete information will not help you perform efficiently or to advance; it is likely to be a waste of time, and may even be seriously misleading.

Training films available to naval personnel are a valuable source of information on many technical subjects. Films that may be of interest are listed in the United States Navy Film Catalog, NavAir 10-1-777.

In addition to the sources of information previously listed and the Reading List, there are many helpful publications issued by various departments of the Navy, Air Force and Army, and the Federal Aviation Administration. Various lists of publications, divided by general subject matter, are available through the Government Printing Office. Listings of publications issued by the Naval Air Systems Command are found in NavAir 00-500 (Series) and NavSup 2002 (Series) lists. Federal Aviation Administration publications are available through the Naval Oceanographic Office and may be requisitioned in accordance with OCEANAV Instruction 5604.1. Chapter 14 of this manual, which includes a discussion of various publications applicable to the AC rating is a good source of reference material. Additionally, publications appropriate to specific subject material are referenced throughout this training manual.

10411

the normal discharge of the grid capacitor reduces the grid voltage after a cycle of operation, but the discharge is to a minus 50 volts, so the circuit does not again conduct without another trigger pulse.

The positive trigger pulse is applied to the grid. The output may be taken from the plate, where a large negative pulse is available, or from a third transformer winding where a pulse similar to the plate pulse can be obtained with either polarity.

Use As a Pulse Sharpening Circuit

The driven or blocked oscillator is useful as a pulse sharpening circuit. A typical radar may use the circuit in figure 14-4 to improve the pulse shape from the phantastron. The phantastron produces the negative square wave pulse labeled input waveshape. This square wave is amplified and becomes the input to the differentiating transformer shown in the circuit. The waveshape at the secondary of the transformer is a peaked wave, as shown in the second waveshape, but because of the inherent imperfections in the trailing edge of the phantastron pulse, the peaked wave due to the trailing edge is not a sharp one. For precise triggering of the circuits following the phantastron, a sharper pulse is required. Therefore the peaked wave is applied to the blocked oscillator.

In place of the voltage divider from plus 250 volts used in the earlier circuits, a long time constant in the cathode circuit provides the cutoff voltage. After several cycles of operation, the grid current, due to positive grid voltages, charges the cathode capacitor. The capacitor discharges slowly between cycles and is recharged with each cycle. The RC combination in the grid circuit (resistance and distributed capacity) is rather short and cannot hold the grid below cutoff for the several hundred microseconds required between pulses.

The negative pulse at the leading edge of the square pulse does not affect the already cutoff tube. The positive pulse at the trailing edge causes the left tube to conduct. The current through the transformer and associated magnetic field induces a positive voltage at the grid of tube V2. This starts a regenerative action in the blocking oscillator associated with tube V2 and it goes through a normal cycle of operation. Meanwhile the pulse ends at the grid of tube V1, and with no other voltage on the grid, the tube is cut off again.

Figure 14-4.—Blocked oscillator used as a pulse sharpening circuit.

1038 1038

CHAPTER 2

MILITARY AIRCRAFT DESIGNATION AND CHARACTERISTICS

Aircraft performance differences have a direct effect on the airspace needed to perform certain maneuvers such as the overhead break, turn to base leg, airspeed on final approach to land, etc.

Good landings are spawned in the approach to the runway; and although pilot technique is the major factor, correct instructions and information issued by controllers will significantly assist pilots to obtain the desired results. When landings and takeoffs are smooth or normal, orderly movements of air traffic at the airport are enhanced.

Information concerning types of aircraft is received from various sources providing flight data on expected and actual aircraft movements. The AC must be able to mentally translate this information into a workable estimate of performance characteristics upon which air traffic control instructions and information are issued. This mental process must necessarily begin with familiarity with the DOD controlled aircraft designation system, and should mature with experience and association with the various aircraft the DOD operates.

MILITARY AIRCRAFT DESIGNATION

All aircraft used by DOD agencies have been assigned designations to conform to joint regulations. The system covers all current and newly designed military aircraft, rockets, and guided missiles, and applies to all elements of the military departments.

All military aircraft are assigned designations consisting of a combination of significant letters and numbers as described in the following paragraphs and tables.

STATUS PREFIX SYMBOLS

The status prefix symbol (letter), if applicable, indicates an aircraft being used for experimentation and special or permanent test. The status letter is placed at the immediate left of the modified mission symbol or the mission or type symbol if no modified mission symbol is applicable. Examples of the use of a status prefix symbol include the X-15, which is an experimental rocket powered aircraft; the X-22A, which is an experimental vertical/short takeoff or land (V/STOL) aircraft; and the YAT-37D, which is an Air Force T-37 reworked and modified for evaluation as an attack aircraft. Status prefix symbols authorized for use are listed in table 2-1.

MODIFIED MISSION SYMBOLS

The modified mission symbol consists of a prefix letter placed at the immediate left of the basic mission or type symbol. Each military department determines the need for the assignment of such symbols. Only one modified mission symbol is used in any one designation. Some examples of the use of the modified mission symbols are as follows: QF-9G, which is an F-9 aircraft equipped as a drone, as indicated by the Q; RA-5C, which is the A-5 aircraft, (fig. 2-1) modified as a reconnaissance aircraft, as indicated by the R. Modified mission symbols authorized for use are listed in table 2-2.

BASIC MISSION SYMBOLS

A basic mission symbol (letter) is used to denote the primary function or capability of an aircraft. Mission symbols denote the mission of the aircraft. Examples of the use of basic symbols for aircraft illustrated in figure 2-1 are a P-3's mission is patrol; a T-2's mission is trainer, etc. The basic mission symbols authorized for use are listed in table 2-3.

104121

Table 2-1.—Status prefix symbols.

Letter	Title	Description
G	Permanently grounded.	An aircraft permanently grounded, utilized for ground instruction and training.
J	Special test, temporary.	Aircraft on special test programs by authorized organizations on bailment contract having a special test configuration or whose installed property has been temporarily removed to accommodate the test. At completion of the test, the vehicle will be returned either to its original configuration or to standard operational configuration.
N	Special test, permanent.	Aircraft on special test programs by authorized organizations on bailment contract, whose configuration is so drastically changed that return of aircraft to its original configuration or conversion to standard operational configuration is beyond practicable or economical limits.
X	Experimental.	Aircraft in a developmental, experimental stage where basic mission and design number have been designated but not established as a standard vehicle for service use.
Y	Prototype.	Aircraft procured in limited quantities to develop the potentialities of the design.
Z	Planning.	Designations used for identification purpose during the planning or predevelopment stage.

TYPE SYMBOLS

Type symbols (letters) are used to denote the type of aircraft if other than fixed wing. Where applicable, type symbols are placed immediately to the right of the basic mission symbol. An example of the use of a type symbol among the aircraft depicted in figure 2-1 is the SH-3 the H meaning helicopter, while the basic mission symbol S denotes antisubmarine. Type symbols authorized for use are listed in table 2-4.

DESIGN NUMBERS

Numbers are assigned consecutively for each basic mission or type. New design numbers are assigned when an existing aircraft is redesigned to an extent that it no longer reflects the original configuration or capability; for example, F-4, F-5, F-8, F-9, A-3, A-4, A-5, A-6, and A-7, with the numbers being the design numbers. The design number is that number assigned to a particular design; and since this joint DOD system is relatively new, it does not necessarily date aircraft presently in use. For instance, the F-9 has been in use much longer than the F-4.

SERIES SYMBOL

A letter is assigned to each series change of a specific basic design. In designating new aircraft, the series symbol is in consecutive order, starting with the letter A. The series symbol is placed immediately to the right of the design number in the aircraft designation. To avoid confusion, the letters I and O are not used as series symbols.

DESIGNATION

All aircraft designations consist of the following: Basic mission symbols and type symbols, if applicable, which denote the primary function or capability of the aircraft; a design number assigned in sequence to each aircraft intended to fulfill the mission; and a series symbol which identifies each change of a specific basic design. A hyphen (-) is always inserted between the basic mission symbol and the design number.

10 [redacted]

AC. 2

Figure 2-1.—Military aircraft.

10414

Table 2-2.—Modified mission symbols.

Letter	Title	Description
A	Attack.	Aircraft modified to search out, attack, and destroy enemy land or sea targets, using conventional or special weapons. This is also used for interdiction and close air support missions.
C	Cargo/Transport.	Aircraft modified for carrying cargo/passengers or medical patients.
D	Director.	Aircraft modified for controlling a drone aircraft or a missile.
E	Special Electronic Installation.	Aircraft modified with electronic devices for employment in one or more of the following missions: (1) Electronic countermeasures. (2) Airborne early warning radar. (3) Airborne command and control, including communications relay. (4) Tactical data communications link for all nonautonomous modes of flight.
H	Search Rescue.	Aircraft modified and equipped for performance of search and rescue missions.
K	Tanker.	Aircraft modified and equipped to provide in-flight refueling of other aircraft.
L	Cold Weather.	Aircraft modified for operation in the arctic and antarctic regions; includes skis, special insulation, and other ancillary equipment required for extreme cold weather operations.
M	Missile Carrier.	Aircraft modified for carrying and launching guided and nonguided missiles as part of the weapon system.
Q	Drone.	Aircraft modified to be controlled from a point outside the aircraft.
R	Reconnaissance.	Aircraft modified and permanently equipped for photographic and/or electronic reconnaissance missions.
S	Antisubmarine.	Aircraft modified so that it can function to search out, identify, attack, and destroy enemy submarines.
T	Trainer.	Aircraft modified and equipped for training purposes.
U	Utility.	Aircraft, having small payload, modified to perform miscellaneous missions, such as carrying cargo or passengers, towing targets, etc.
V	Staff.	Aircraft modified to provide accommodations such as chairs, tables, lounge, berths, etc., for the transportation of staff personnel.
W	Weather.	Aircraft modified and equipped for meteorological missions.

10415 1101

Table 2-3.—Basic mission symbols.

Letter	Title	Description
A	Attack.	Aircraft designed to search out, attack, and destroy enemy land or sea targets, using conventional or special weapons. This is also used for interdiction and close air support missions.
B	Bomber.	Aircraft designed for bombing enemy targets.
C	Cargo/Transport.	Aircraft designed for carrying cargo/passengers or medical patients.
E	Special Electronic Installation.	Aircraft equipped with electronic devices for employment in one or more of the following missions: (1) Electronic countermeasures. (2) Airborne early warning radar. (3) Airborne command and control including communications relay. (4) Tactical data communications link for all nonautonomous modes of flight.
F	Fighter.	Aircraft designed to intercept and destroy other aircraft and/or missiles (includes multipurpose aircraft also designed for ground support missions). For example, interdiction and close air support.
K	Tanker.	Aircraft designed for in-flight refueling of other aircraft.
O	Observation.	Aircraft designed to observe (through visual or other means) and report tactical information concerning composition and disposition of enemy forces, troops, and supplies in an active combat area.
P	Patrol.	Long-range, all-weather, multiengine aircraft operating from land and/or water bases designed for independent accomplishment of the following functions: antisubmarine warfare; maritime reconnaissance; and mining.
R	Reconnaissance.	Aircraft designed to perform reconnaissance missions.
S	Antisubmarine.	Aircraft designed to search out, detect, identify, attack, and destroy enemy submarines.
T	Trainer.	Aircraft designed for training personnel in the operation of aircraft and/or related equipment, and having provisions for instructor personnel.
U	Utility.	Aircraft used for miscellaneous missions, such as carrying cargo and/or passengers, towing targets, etc. These aircraft will include those having a small payload.
X	Research.	Aircraft designed for testing configurations of a radical nature. These aircraft are not normally intended for use as tactical aircraft.

10416

Table 2-4. —Type symbols.

Letter	Title	Description
H	Helicopter.	A rotary-wing aircraft designed with the capability of flight in any plane. For example, horizontal, vertical, or diagonal.
V	VTOL and STOL.	Aircraft designed for vertical takeoff or landing with no takeoff or landing roll, or aircraft capable of takeoff and landing in a minimum prescribed distance.

In the aircraft designation A-6A, for example, the A followed by a hyphen (-) indicates that the aircraft is designed for an attack mission, as shown in table 2-3. The number 6 has been assigned to this particular design for an attack mission. The letter A following the number 6 indicates that this is the first series of this design. The designation A-6B would identify the first series change of the basic design.

Aircraft designators may be expanded to indicate an added or restricted capability by the use of one of the modified mission symbols (table 2-2) preceding the basic mission symbol. In the designation A-6B, for example, the prefix letter K placed to the immediate left of the basic mission symbol would identify the KA-6B as an A-6B which has been modified to provide in-flight refueling. When modified mission symbol E is added to A-6B, the resulting term EA-6B can be identified as an A-6B which has been modified with a special electronic installation.

A status prefix symbol may be added to the designation to indicate aircraft being used for experimentation and for special or service testing. (See table 2-1.) The status letter, if used, is placed at the immediate left of the basic mission symbol or the modified mission symbol. The designation JEA-6B would be identified as an aircraft with the same capabilities as the EA-6B but temporarily configured for a special test program; at the completion of the test, the vehicle will be returned to the original configuration.

PERFORMANCE AND MANEUVERABILITY

In addition to being able to visually identify various types of aircraft, AC's must familiarize themselves with aircraft operating characteristics. New aircraft with increased speed and performance capabilities must operate within the same airspace as older, slower aircraft. This presents a problem in all aspects of air traffic control, not only from the standpoint of faster aircraft overtaking slower aircraft but also in regard to the maneuvering area, stalling speed, rate of climb, and other factors which should govern the AC's judgment under various conditions. Since the AC often gives instructions based on visual observations of air traffic in a particular area, it is evident that mistaken calculation of aircraft performance and maneuverability characteristics could lead to confusion for both pilots and controllers.

The control tower operator issues clearances that in his opinion can be safely followed without collision hazard if reasonable caution is exercised by the pilot. The clearance issued is permissive in nature and does not relieve the pilot of the responsibility for cautious handling of his aircraft. The information and clearances issued are intended to aid pilots to the fullest extent in avoiding collisions; this goal requires correct and concise instructions based on sound judgment for an effective flow of air traffic.

Normally, single-engine aircraft (as a class) are comparatively small and require less operating space around the airport than the large multiengine aircraft. However, some of the single-engine jet aircraft do require a rather wide approach due to their high landing speeds.

Multiengine aircraft (as a class) are normally larger than the single-engine types. They require approaches that are much wider and a final approach which is much longer. Each is a separate landing or takeoff problem as they rarely perform these functions in formation; whereas, in the case of the single-engine aircraft, many landings and takeoffs are completed in formation.

It is difficult to make generalizations concerning the performance and maneuverability of various aircraft, as each type has its own set of characteristics governing its performance both in the air and on the ground. Jet aircraft as a

10417
01F01

type require less warmup time than reciprocating engine types. The jets are extremely uneconomical to operate on the ground and at altitudes under those for which they were designed to operate. Their landing and takeoff speeds are universally higher, many requiring the use of drogue chutes for landing and afterburners for takeoff on most present-day airfields. Field elevations and runway temperatures are vital elements in control of jet aircraft and, to a somewhat lesser degree, in the control of reciprocating engine aircraft. As an example of what effect altitude has on even a light aircraft, it may be startling to learn that an aircraft of this type which has a rate of climb of 420 feet per minute at sea level has its rate of climb reduced to 225 feet per minute at 5,000 feet. Also, the distance needed for takeoff is doubled between these two altitudes. (See fig. 2-2.) Higher temperatures and higher humidity have similar effects on aircraft performance. A high-performance jet fighter quite possibly may not operate from an airfield with short runways on a day on which high runway temperatures prevail, even though the field elevation is only moderately high. Later in the afternoon, or at night, the same fighter may be able to effect a takeoff from the same field, because the atmosphere becomes more dense during night hours as a general rule. More lift is afforded the aircraft in dense air, be it a light aircraft or a high-performance jet.

An understanding of the large quantities of fuel consumed by our present-day jet type aircraft is of great importance to the Air Controlman. Whether it be with respect to taxiing for departure, landing, or local flying, a working knowledge of the characteristics of the jet and its fuel problem will put the jet into the traffic

AC.3

Figure 2-2.—Comparison of takeoff distances with increased altitude.

10418

picture without any special priority. A jet engine consumes 10 to 20 times as much fuel as the average reciprocating engine while operating on the ground. For example, a T-33 will consume 4 gallons of fuel per minute at idling speed while on the ground. At 40,000 feet, and using 100 percent power, it consumes 4 gallons per minute and travels 6 to 7 miles.

Cognizance of the hazards to aircraft on the ground and in the air, which are caused by wake turbulence from heavy aircraft, is of the utmost importance to the Air Controlman. Large aircraft can create wake turbulence severe enough to endanger light aircraft, particularly in light wind conditions, as this turbulence may remain in the approach and landing area for several minutes. Turbulence may be encountered by lightweight and mediumweight aircraft when landing or crossing the wake of large aircraft. More detailed information concerning wake turbulence can be found in chapter 11 of this Rate Training Manual. The turbulence created by a jet aircraft without afterburner at 100 percent rpm may extend from 150 feet to 200 feet, while the same jet with afterburner may create turbulence from 300 feet to 400 feet. These areas may vary with atmospheric conditions. If the jet is moving, the area extends farther than if the jet is holding. The blast effect of a present-day large jet engine is extremely dangerous. For example, at a distance of 25 feet temperatures may reach 350 degrees with a velocity of 475 miles per hour, while at 100 feet the temperature may still be about 100 degrees with a velocity of 50 miles per hour.

The installation of high-speed or banked turnoffs is an important factor in the expeditious handling of arriving traffic. Pilots are able to clear the runway in use in a much shorter time than was possible with the earlier runway and taxiway configuration. This in turn is of tremendous assistance to the Air Controlman in expediting the flow of traffic. Taxiways at many airports are too narrow for use by our larger aircraft today. Consequently, remodeling and new construction are constantly being done to cope with the larger and heavier aircraft, as well as those planned for the future. The new taxiways have banked, high-speed turnoffs wide enough to accept aircraft at faster speeds. When installed and in use, high-speed turnoffs have been reported used at speeds up to 63 miles per hour.

The Air Controlman must remain alert to remember all of the performance and maneuverability characteristics needed to handle successfully all types of aircraft which may come under his control. As new types of aircraft are placed in service, he should immediately learn as much about them as possible.

When the pilot of a high-performance aircraft calls in for landing instructions, the Air Controlman must give the pilot a precise and correct set of instructions. These instructions should contain and be based on a great number of determinations made quickly by the Air Controlman. First of all, he has to recognize the aircraft and mentally review the performance characteristics associated with this aircraft. When the proper mental associations have been made, he is ready to give the pilot the necessary correct instructions. His mental review should be concerned with such characteristics as the aircraft's landing speed, approach patterns, runway length requirements, barometric pressure, and many others connected with the safe approach and landing of this aircraft.

AIRCRAFT CHARACTERISTICS

The following paragraphs contain certain characteristics that should be known by individuals controlling aircraft, such as those illustrated in figure 2-1. Keep in mind that memorizing the exact figures is not important, but they are used in this text to show the type of comparison a controller would make when issuing instructions. If all aircraft in your landing pattern were high performance aircraft, then spacing problems of one aircraft relative to another would be less than is the case when high performance and cargo type, for instance, are using the same runway.

The A-4 is considered a high performance aircraft with a cruising speed in excess of 500 knots at altitude. Its approach speed is comparable to the A-6 type aircraft. One problem of particular importance is the effect of a crosswind on landing due to the configuration of the landing gear. Pilots of A-4's are listening intently for the wind direction and velocity since the gear is rather high and close together and presents a problem of stability after the aircraft has touched down on the runway under crosswind conditions.

The A-7 resembles the F-8 aircraft, is a high performance type, and also cruises in excess of 500 knots at altitude. The A-7 lands rather fast with a final approach speed of

10419

approximately 120 knots which is comparable to the F-8 also.

The F-8 is really a high performance aircraft with the F-8D and E series capable of nearly Mach 2 (Mach 1 = speed of sound at sea level). Its adjustable wing allows it to slow down for the low and slow landing operation.

The A-6 has a cruising speed of about 420 knots but is an extremely stable aircraft at landing speed with a stall speed of about 70 knots, which is comparable to the E-2. This would allow the A-6 to mix with the slower types of aircraft without too much concern about overtaking other traffic.

The F-4 is a high performance aircraft with a maximum speed of over Mach 2. Its approach speed is about 120 knots, which is comparable to most jet fighter type aircraft. Two engines with afterburners enable it to take off in about 5,000 feet, while it has good slow down capability when back on the runway by being able to land in about 3,000 feet.

The P-3 has four turboprop engines and can take off in about 3,700 feet and climb at a rate of 1,500 feet per minute. It cruises at approximately 350 knots at altitude and has good endurance capability, being able to operate for 17 hours on two engines. It also has reversible pitch propellers which enable it to stop in a short distance after landing, for a quick turn off the duty runway.

The RA-5C is another high performance aircraft with a maximum speed of over Mach 2. Its approach speed, takeoff, and landing characteristics are comparable to the F-4.

The T-2 is a jet trainer aircraft and is fairly fast with a cruising speed of over 450 knots but with the straight wing design for more stable training operations and slower landing speeds.

The E-2 is a turboprop aircraft with a cruising speed of approximately 280 knots. It can slow down very effectively for the landing approach with a stall speed of approximately 70 knots.

The C-130 also has four turboprop engines and is a cargo type aircraft with a cruising speed of approximately 350 knots. It lands a little faster than the E-2 with a stall speed of approximately 100 knots. It can take off in about 3,500 feet and with the reversible pitch propellers can land and stop in about 2,200 feet. This enables it to clear the runway unusually fast for a large aircraft.

CHAPTER 3

FLIGHT PLANNING AND FLIGHT ASSISTANCE SERVICE

FLIGHT PLANNING

Planning is important in anything that we do. Where flying is concerned, inadequate or incorrect planning can seriously jeopardize the safety of the flight to the point of causing destruction to property, serious injury, or even disaster. As an Air Controlman, you are directly concerned in assisting pilots in the planning and proper clearance of their flights.

PREFLIGHT ACTION BY PILOTS

Federal Aviation Regulations Part 91.5 states that:

"Each pilot in command shall, before beginning a flight, familiarize himself with all available information concerning that flight. This information must include, for a flight under IFR or a flight not in the vicinity of an airport, available weather reports and forecasts, fuel requirements, alternatives available if the planned flight cannot be completed, and any known traffic delays of which he has been advised by ATC."

OpNav Instruction 3710.7 (Series) also states that:

"Except in emergencies and flights of combat necessity wherein conditions do not permit, pilots shall insure that all preflight planning needed for the prosecution of a safe and properly conducted flight has been accomplished prior to carrying out any type of flight in a naval aircraft."

Although the primary responsibility for planning the safe conduct of a flight rests with the pilot in command, you as an Air Controlman, share the overall responsibility. This is accomplished by providing the most efficient service possible. Charts and publications must be available and up to date. Materials and necessary forms must be adequate and easily accessible. You must keep yourself informed about recent changes, additions, or deletions of any material or service affecting air traffic control and be ready to supply the information needed.

FLIGHT CLEARANCE AUTHORITIES

The authority and responsibility for clearance of aircraft flight at naval air stations are vested in the commanding officer. Commanding officers may delegate authority to commissioned officers, warrant officers, and aviation pilots under their command whom they consider qualified to exercise such authority. Detailed responsibilities and procedures are found in OpNav Instruction P3710.7 (Series).

Pilots having a special instrument rating are authorized to approve a flight clearance for any flight of a naval aircraft in which they fly as pilot in command or as flight leader of a formation flight.

FLIGHT CLEARANCE FORMS

The pilot in command of a naval aircraft or group of aircraft proceeding as a unit must prepare and submit a flight clearance form prior to every flight except for the following cases:

1. Flights of combat necessity.
2. Student training flights under the jurisdiction of Naval Air Training Command for which adequate flight guard is provided.
3. SAR flights when there would be undue delay in the accomplishment of the mission.

DD Form 175

A DD-175 is a military flight plan and must be used for all point-to-point and round-robin (departure and destination are the same) flights from U.S. military airfields and civil airfields at which a military operations department is located. (See fig. 3-1.)

104211

Tube V1 is an amplifier and isolation circuit which causes the blocking oscillator to start very soon after the trigger pulse arrives, then disconnects the triggering circuit from the blocking oscillator so it can go through its normal cycle unaffected by the triggering circuit.

The output is taken from a small resistor above the transformer in the plate lead. A sharp negative pulse of low amplitude is produced across the resistor.

COUNTING CIRCUITS

A counting circuit is one which receives uniform pulses, representing units to be counted, and produces a voltage proportional to their frequency. By slight modifications the counting circuit is used in conjunction with a blocking oscillator to produce a trigger pulse which is a submultiple of the frequency of the pulses applied.

The pulses applied to the counting circuit must have the same amplitude and time duration if accurate frequency division is to be made. Counting circuits, therefore, are ordinarily preceded by shaping and limiting circuits to insure this uniformity of amplitude and width. Under these circumstances the pulse-repetition frequency constitutes the only variable and frequency variations may be measured.

POSITIVE COUNTER

Positive pulses, which may vary only in their recurrence frequency, are applied to the input of the positive counter as shown in figure 14-5.

The charge on the coupling capacitor C1 cannot change instantaneously as the positive leading edge is applied, so the plate of V2 becomes positive and the diode conducts. A charging current flows through R1 during the pulse time and a small charge is developed on C1. At the end of the pulse the change in voltage places the diode side of the capacitor at a negative potential equal to the charge accumulated on C1.

Tube V2 cannot conduct, as its plate is negative with respect to its cathode. However, V1 conducts, discharging the small charge from the capacitor, which would otherwise build up during each succeeding positive pulse, eventually rendering the circuit insensitive to the applied pulses.

Figure 14-5.—The positive counter.

Circuit Controlled by Positive Counter

Since a certain amount of current flows through R1 each time a pulse is applied, an average current flows which increases as the pulse recurrence frequency increases and decreases as this frequency decreases. The IR drop developed across R1 can be used to control a succeeding stage as is illustrated in the circuit controlled by a positive counter (fig. 14-6).

The filter in the grid circuit of V3 aids in obtaining smooth operation by removing too rapid changes in voltage developed across R1. The voltage developed across R1 is the average

Figure 3-1.—DD Form 175.

C 10622

DD Form 175-1

A DD Form 175-1 (fig. 3-2) is a flight weather briefing form completed by weather service personnel for a pilot. It is used for all point-to-point and round-robin flights. The DD-175-1 is used in conjunction with a specific DD-175 for which it is completed. The DD-175-1 need not be used on VFR flights provided that the following certification is made on or attached to the DD-175.

BRIEFING VOID (time) Z. FLIGHT AS PLANNED IS CERTIFIED VFR WITH NO DANGEROUS WEATHER EN ROUTE. VERBAL BRIEFING GIVEN.

_____
(Signature of forecaster.)

AC's should assist pilots in insuring that the weather briefing is still valid at takeoff. The weather briefing void time is normally one-half hour after estimated time of departure (ETD). Except under unusual circumstances, this should not exceed 2 hours from the actual time of weather entries on the DD-175-1. Methods of checking weather briefing void times vary between facilities, but most require that the void time be included on the flight progress strips (discussed later in this chapter) used to maintain a file of current air operations.

Local Flight Clearance

Clearance authorities may authorize the use of the daily flight schedule or an abbreviated DD-175 signed by the pilot in command, with the word LOCAL contained in the route of flight block, for clearing aircraft for flight within the established local flying area and adjacent offshore training areas provided that the following conditions apply:

1. Sufficient information is included to satisfy the needs of the local clearance authority which guards the flight.
2. Base operations maintains cognizance of each flight and is responsible for initiating any overdue action or inflight advisory service necessary.
3. Completed flight schedules are retained in base operations files for 90 days.
4. Flights are not conducted IFR within controlled airspace except as jointly agreed upon in writing between the local command and the air traffic control agency concerned.

Foreign Clearance Forms

Flights proceeding from or occurring outside the U.S. at other than U.S. military air facilities must use the flight clearance form required by foreign authorities.

GENERAL FLIGHT CLEARANCE PROCEDURES

Proper identification verifying their status must be shown by all passengers prior to being furnished air transportation. Except for ranking civilian officials, civilian passengers must present a copy of the orders authorizing travel in military aircraft and may be required to complete a Release from Claim for Injury or Death form.

Modification of a flight clearance form may be accomplished only with concurrence of the pilot in command.

Point-to-point flights may be changed to local flights by filing a local flight plan in the air after arrival over destination.

Estimated Time En Route

For the purposes of flight clearance, estimated time en route is defined in the following paragraphs.

VFR FLIGHT.—The time from takeoff to a position over the destination airfield, including known or preplanned en route delays.

IFR FLIGHT.—Total planned time from takeoff to time over the initial approach fix to be used at the destination airport, which is listed as the last fix en route on the flight plan exclusive of the time anticipated for en route delays, such as practice approaches, landings, etc. En route delays are listed in the remarks section.

STOPOVER FLIGHT.—For stopover flights, the ETE is calculated in the same manner as for VFR or IFR flights except that each stopover point may be considered a destination for the purposes of the ETE calculation. The ETE for each leg of such flights is listed on the flight plan opposite the route of flight. The following conditions apply:

1. For IFR stopover flights, each leg is listed on a separate line on the proposed flight plan along with altitude/FL, etc., necessary for obtaining an IFR clearance on subsequent legs.

2. If an ATC clearance is required for a second or subsequent leg of a stopover flight, the pilot just advise the tie-in FSS serving the next stopover point of his estimated time of departure (ETD) from that airport to initiate a request for an IFR ATC clearance for the second or subsequent legs.

3. For all stopover flights, a VOID time is entered in remarks. Such VOID times are computed by adding the ETE for each leg of the flight and the total estimated ground time for all stopovers to the ETD as entered on the flight plan.

4. A NOTAM and weather briefing must be completed at the original departure point for the entire flight. At each intermediate stop the pilot must recheck the weather to insure that the next point of intended landing is at or above landing minimums.

5. En route stops are not authorized on a DVFR type flight in the continental U.S. They may be authorized in overseas areas depending upon agreement between naval commands, air traffic control authority, and the cognizant air defense command.

Estimated Time of Arrival (ETA)

Determining an ETA of an aircraft is simply done by adding the estimated time en route (ETE) to the actual departure time. Normally, the ETA will apply to the final destination; however, on stopover flight plans, the ETA is determined for the first intermediate stopover destination by departure station. Then the intermediate stations become departure stations upon receipt of a departure time and will determine an ETA for transmission to the next stopover or final destination as appropriate.

Mandatory Information to
Flight Service Agencies

The pilot in command of a flight is responsible for assuring that the appropriate flight service agency will be furnished with the essential elements of the flight plan as initially approved and a takeoff report. Delivery of a properly prepared flight clearance form to duty personnel at an established base operations office at the point of departure relieves the pilot of such responsibility. The local clearance authority must then insure that the appropriate flight service agency is furnished the flight plan and takeoff report by duty personnel upon acceptance of the flight clearance form.

The pilot in command is also responsible for assuring that the appropriate flight service agency will be furnished a landing report (close-out) upon arrival at destination. Delivery of a copy of an executed flight clearance form to destination base operations duty personnel satisfies this responsibility. The local flight clearance authority must then insure that duty personnel furnish the appropriate flight service agency with the landing report upon acceptance of the flight clearance form.

Handling of Flight Clearance
Forms by Naval Facilities

Original clearance and weather forms filed at departure station flight clearance offices and duplicate copies of clearance and weather forms turned in to destination station flight clearance offices must be retained for a period of 3 months, after which they may be destroyed.

Shore/Ship Operations

Prior to flight from a shore activity to a ship operating in an offshore area when a landing aboard the ship is intended, the pilot in command must file a flight plan. A DD-175 is required for IFR flight. A daily flight schedule may be used for VFR flight.

Prior to flight from a ship operating in an offshore area to a shore activity where a landing is intended, the pilot in command must file a flight plan with the ship. The ship will relay the flight plan to the shore activity. If no communications link is available, the pilot should file his flight plan with the nearest shore activity by radio as soon as possible after takeoff.

Clearing authorities, and subsequently duty personnel at base operations, are responsible for insuring timely handling of flight movement information for each ship/shore operation.

Flight suspense for search and rescue purposes becomes the responsibility of the destination activity after acknowledging receipt of a flight plan.

When such flights will penetrate or operate within an ADIZ or DEWIZ (discussed in chapter 9) the appropriate air defense command must also be informed of the operation.

FLIGHT PLAN CODES

Various codes are established concerning highest rank aboard, VIP honors requested, and

cargo/passenger control information for the purpose of brevity when processing information contained in the remarks section of a DD-175. (See fig. 3-1.) AC's are responsible for insuring that timely action is effected and appropriate personnel are made aware of such information.

Since these codes are quite lengthy and subject to relatively frequent changes, they are not listed in this training manual. The AC should refer to a current edition of Flight Information Publication, Planning, Section II, for accurate and complete information contained in flight plan codes. OpNavInst. 3722.8 (Series) is also a good reference for flight plan codes.

FLIGHT PACKETS

A thorough knowledge of the contents, maintenance, and assembling of flight packets is another important duty performed by Air Controlmen. These flight packets (or nav kits, as they are more commonly called) are vitally important to each pilot as he prepares to depart on most types of flights. However, the mission of the flight, type of aircraft utilized, and the geographical location of the station cause the contents of the flight packet to vary.

Flight packets are maintained in Flight Clearance for station aircraft only; that is, aircraft for which the station commanding officer is reporting custodian or for which he has responsibility. This usually limits the number of flight packets to 5 or less. Squadrons, units, etc., based at the facility maintain their own flight packets for their use.

Normally, the pilot or a representative of his crew stops at the flight planning room to obtain a flight packet prior to preparing his flight plan. Figure 3-3 is a sample flight packet checklist. This form can be expanded or shortened to meet the needs of the station. The pilot or his representative when presented one of these forms fills out the top portion. Then the Air Controlman can quickly assemble those items that the pilot or his representative has indicated as being required for the particular flight. Normally, the items necessary to complete a flight packet are carried in a brown leather briefcase or other suitable container. A checklist such as shown in figure 3-3 not only allows the pilot or his representative to select the items deemed necessary for the flight but also greatly reduces the chance of an item being left out. In addition, the form serves as a temporary custody receipt. This is very important, as the value of the items that might be included in a flight packet may vary from a few cents to several hundred dollars.

FLIGHT ASSISTANCE SERVICE

An agreement between the FAA and Department of Defense (DOD) provides that the FAA assume certain communications functions dealing with military flight plans and related messages. Designated FSS's, called tie-in stations, are connected to adjacent military bases by local interphone for handling traffic. This does not include flights to or from carriers, which are handled via Navy communications.

COMMUNICATIONS SYSTEMS

The FAA uses a teletype system called Service B to handle communications requirements of aircraft movement and control messages. The system consists of two separate teletype networks, Area B and Center B. Area B circuits are generally arranged to serve ARTCC areas in the conterminous U.S. All FSS's are on an Area B circuit and those FSS's designated as tie-in stations actually enter military messages on the FAA teletype circuit for adjacent military bases. ARTCC's use Center B to handle emergency and IFR movement and control messages addressed to other centers.

A related circuit, called Military B, connects most base operations with ARTCC's for transmitting proposed IFR flight plans.

The FAA uses two interphone systems for the purpose of rapid voice communications. Service F is an interphone system which connects ARTCC's and associated terminal facilities for handling IFR movement and control messages which are time critical. Flight Service Interphone is the landline connection between tie-in stations and adjacent military bases to handle messages between such stations for entry into the Area B teletype circuit.

Interphone Operating Procedure

The equipment used with interphone systems varies according to local requirements; i.e., loudspeaker, handset, headset, manual signaling by use of pushbutton, key or dial, etc. Generally, naval facilities have a loudspeaker at the necessary control positions which must be monitored continuously since they will be called by voice. To call the center or flight service (tie-in

PILOT'S SIGNATURE	DATE

AC.6

Figure 3-3—Flight packet checklist.

FSS), there is usually a pushbutton or dial to engage which activates a buzzer or light at the facility called. There may be several stations on one circuit, all of which may be called by voice except the center or flight service. Each termination on the line has a transmit and receive capability. Voice recorders may be installed to monitor and record the systems.

Standard phraseology must be used on the interphone systems. Messages are terminated with operating initials (locally assigned all AC's). The following are examples of interphone operation:

1. Tower . . . .(Signals the center manually).
   Center . . . .OAKLAND CENTER.
   Tower . . . .ALAMEDA TOWER,

10477101

REQUEST CLEARANCE NAVY SIX ONE EIGHT THREE FOUR.

Center . . . .ATC CLEARS NAVY SIX etc. . . .MB (operating initials).

Tower . . . .BR.

2. Center . . . .BRUNSWICK APPROACH CONTROL, BOSTON CENTER, ESTIMATE.

Approach Control . . . .BRUNSWICK APPROACH CONTROL, GO AHEAD.

Center. . . .NAVY ONE TWO ONE SIX ONE, ESTIMATING etc. . . .RW

Approach Control. . . .ST.

3. FSS. . . .WHITING OPERATIONS, FLIGHT SERVICE, FLIGHT PLAN.

Operations. . . .WHITING OPERATIONS, GO AHEAD.

FSS. . . .NAVY SIX ONE TWO ONE TWO, FLIGHT OF THREE etc. . . .WW.

Operations. . . .AZ.

4. Operations. . . .(Signals flight service manually)

FSS. . . .FLIGHT SERVICE.

Operations. . . .NORFOLK OPERATIONS, ARRIVAL.

FSS. . . .GO AHEAD.

Operations. . . .(arrival message) CB.

FSS. . . .BC.

Clear enuciation is necessary at all times. Words should be spoken directly into the interphone instrument in a moderate tone of voice. The transmitting operator should not speak faster than the receiving operator can accurately copy. Spelling is not necessary unless a word is peculiar or seldom used. When spelling is necessary, use the phonetic alphabet discussed in chapter 10 of this Rate Training Manual.

PRIORITY OF INTERPHONE COMMUNICATION.—Only those messages necessary for air traffic control, contributing to air safety, or directly related to aircraft movements, are authorized on the interphone systems. Priority of such messages is established as follows:

1. First priority—Emergency messages including essential information on aircraft accidents or suspected accidents. After an actual emergency has passed, a lower priority should be given messages relating to an accident.

2. Second priority—Clearances and control instructions.

3. Third priority—Movement and control messages using the following order of preference when possible:

a. Progress reports.

b. Departure or arrival reports.

c. Flight plans.

4. Fourth priority—Movement messages on VFR aircraft.

NOTE: The words EMERGENCY or CONTROL are used for interrupting lower priority messages when necessary.

AC's should refer to OpNav Instruction 3722.8 (Series), and FAA Flight Services Handbook 7110.10 (Series) and TATC Handbook 7110.8 (Series), for possible changes or more detailed information on interphone procedures.

VFR FLIGHT PLAN HANDLING

When a pilot delivers a DD-175 to base operations and subsequently departs, the AC on duty must transmit the necessary information to flight service to be entered on the Area B teletype circuit for transmission to destination. All flights are held in suspense, or kept track of (until the aircraft lands), for the purpose of search and rescue service. The following is a brief discussion of what transpires from departure to arrival to give the AC an idea of the entire operation.

All messages concerning flight movements must be transmitted to flight service within 5 minutes after the required information is received.

Flight Notification Message

After an aircraft has departed or before actual departure for flights of short duration with mutual agreement, the following information from the flight plan must be transmitted to flight service:

1. Type of flight.
2. Aircraft identification.
3. Type of aircraft/special equipment suffix. (Include number and type if a formation flight.)
4. Point of departure.
5. Point of destination.
6. Estimated time of arrival (ETA) at destination.
7. Remarks (VIP and passenger/cargo information).

The FSS will then relay a flight notification message to the tie-in FSS serving the destination airport and will hold the flight in suspense until the destination FSS acknowledges the message. If an acknowledgement for a flight notification message is not received from the destination FSS within the following time limits, FSS personnel may use regular telephone to assure delivery:

10428

1. Before ETA, if estimated time en route (ETE) is 30 minutes or less.

2. 30 minutes after departure if the ETE is between 30 minutes and 2 hours.

3. 1 hour before ETA, if the ETE is 2 hours or more.

4. 30 minutes after departure if the message contains VIP/RON (remain overnight) information.

When destination tie-in FSS acknowledges the flight notification message, the departure FSS then files it in a completed file. The destination FSS relays the message to destination airport and holds the flight in suspense until an arrival report is received from destination airport.

Arrival Reports

Arrival reports are not transmitted to the departure FSS unless an aircraft arrives for which a flight notification message was not received. In such cases, AC's at the destination airport must provide the tie-in FSS with the aircraft identification, point of departure, and time of arrival to be relayed to the departure tie-in FSS and finally to the departure airport. Arrival reports are also required for overseas flights and special military flights of Presidential or Vice Presidential aircraft. An exception is that in Alaska an arrival report is required on a military aircraft when departure is from a military base.

Stopover Flights

Flights which include stopovers en route to final destination are handled basically the same as VFR flights with the following exceptions:

1. The point of the first stopover and an ETA (in lieu of ETA at destination) at that point, followed by each stopover point and ETE in order of stops and destination is included in the original flight notification message.

2. Each intermediate tie-in FSS will:

a. Acknowledge receipt of departure message.

b. Notify Base Ops of the inbound.

c. Suspense the message until an arrival or close out is received or take the necessary action if overdue.

d. When received, forward a departure time to the tie-in FSS for the next stopover point and obtain an acknowledgment.

Destination tie-in FSS will take the same action as the intermediate FSS's except that the flight plan is closed out when an arrival report is received from destination Base Ops, or if no further information, such as departure time, is received from the preceding stopover point by the message VOID time.

SEARCH AND RESCUE (SAR)
PROCEDURES FOR VFR AIRCRAFT

The following is a list of terms or definitions that the AC must be familiar with to better understand SAR procedure.

1. Inland SAR Region . . . The area in which the USAF exercises the SAR coordinating function. It includes all of the inland area within the conterminous U. S. except the waters under jurisdiction of the U. S. Coast Guard for SAR purposes.

2. Air Rescue Center (ARC). . . . The inland SAR region is further divided into three regions; i.e., eastern, western, and central region, each with an established ARC for the purpose of providing command, technical, and administrative assistance to local rescue detachments within its area of responsibility.

3. Maritime Region. . . . The area in which the U. S. Coast Guard exercises the SAR coordinating function, including the territories and possessions of the U. S. and the high seas.

4. Rescue Coordination Center (RCC). . . . A center which coordinates and controls SAR operations as an integral part of each ARC.

5. Alert Notice (ALNOT). . . . Notice given to appropriate facilities and agencies that an aircraft is overdue.

6. Information Request (INREQ). . . . A request for information concerning an overdue VFR aircraft.

Responsibility

The departure station (tie-in station) is responsible for initiating SAR action on flights for which flight plans have been entered into the FAA communications system until receipt of the destination station's acknowledgment of the flight notification message. Then the responsibility is transferred to the destination (tie-in) station. Military operations offices are responsible for initiating action on all other flights.

A VFR or DVFR flight is considered overdue when communication cannot be established with

it and it fails to arrive 30 minutes (15 minutes for jets) after its ETA.

A flight not on a flight plan is considered overdue if a reliable source reports it one hour overdue at destination.

Overdue Aircraft Action

As soon as a VFR aircraft becomes overdue, the destination tie-in station (including intermediate destination tie-in stations for stopover flights) must attempt to locate the aircraft by checking all adjacent airports that can be reached by government circuits or local telephone. If necessary, a long distance telephone call may be made to the destination airport.

If this communications search (FAA's responsibility for SAR is limited to communications and alert) does not locate the aircraft, the signal QALQ is transmitted to the departure tie-in station.

NOTE: Q signals are listed in FAA Flight Service Handbook 7110.10 (Series). The Q signal above is a code for asking if the aircraft in question has landed at the station queried.

Upon receipt of such an inquiry, the departure tie-in station must check locally for any information about the aircraft. The results of the check must then be transmitted back to the destination station.

Information Request (INREQ)

If the aircraft is not located by the inquiry to departure station, the destination station must transmit a numbered INREQ message to stations along the route, to departure station, and to the destination RCC tie-in station (an FSS with interphone to the appropriate RCC) as follows:

1. For aircraft on a flight plan—1 hour after ETA (30 minutes for jets).
2. For aircraft not on a flight plan—1 1/2 hours after ETA.

NOTE: For special procedures peculiar to Alaska and Hawaii, refer to FAA Flight Services Handbook 7710.10 (Series).

En route stations receiving an INREQ must seek information about the aircraft by checking station records and inquiring at all local airports which can be contacted by interphone or telephone. A reply to the INREQ must be sent to the originating station within 30 minutes after receipt even if the report is negative. If a search cannot be completed within 30 minutes, a status report is sent to the originating station followed by a completion report when available.

The departure station has already conducted a local communications check and holds the INREQ message in suspense.

If the aircraft is located by the INREQ, the originator must transmit a numbered message to all original INREQ addressees informing them of the fact.

Alert Notice (ALNOT)

If replies to the INREQ have been negative, or the aircraft has not been located within 1 1/2 hours (2 hours for no-flight-plan aircraft) after ETA, whichever occurs first, the destination station must transmit an ALNOT to the RCC tie-in station and all Area B circuits serving the ALNOT search area.

The ALNOT search area is normally that area extended 50 miles on either side of the proposed route of flight from the last reported position to the destination station. However, if requested by the RCC, or the discretion of the destination station, the ALNOT search area may be expanded to the maximum range of the aircraft.

Upon receipt of an ALNOT, each station whose area of responsibility extends into the ALNOT search area must condcut a communications search of those airports which could accommodate the aircraft and which were not checked during the INREQ search.

Receiving stations must notify the originator within 1 hour after receipt of the results or the status of the search.

If the ALNOT search fails to locate the aircraft or 1 hour has elapsed since transmission, whichever occurs first, the destination station must notify the RCC by message via the RCC tie-in FSS.

The ALNOT remains current until the aircraft is located or the search is suspended by the RCC. The ALNOT originator must then cancel the ALNOT by message on all circuits over which it was originally transmitted. All agencies which have been alerted must be informed.

Information Furnished ARC

All available information about an overdue aircraft must be given the RCC, including:

1. Agency and the person calling.

2. Details of the flight plan, or if the aircraft was not on a flight plan, all the facts about the source of the report.

3. Time of last radio contact, with whom the contact was made, and the frequency used.

4. Last position report.

5. Action taken and proposed action by the reporting station.

6. Positions of other aircraft known to be along or near the route of flight of the missing aircraft upon request.

HAZARDOUS AREAS

When regularly traveled VFR routes cross large bodies of water, swamps, mountains, or other hazardous areas where survival depends upon rapid rescue, a plan may be established by local authorities for special rescue procedures.

Because of the variety of possible situations a standard procedure is not prescribed. Generally these plans depend on a contact every 10 minutes with aircraft crossing these areas. If contact is lost with the aircraft for more than 15 minutes, SAR is alerted.

IFR FLIGHT PLAN HANDLING

Federal Air Regulations require, in part, that a flight plan be filed and an ATC clearance obtained prior to operation within controlled airspace in accordance with instrument flight rules.

When a pilot files an IFR flight plan with base operations, the AC's on duty must transmit the proposed IFR flight plan message to the ARTCC in whose area the IFR flight originates.

The message may be sent to the ARTCC via Military B teletype (Area B may be used through flight service in some cases) if the aircraft's proposed departure time is 30 minutes or more from transmittal time. If time is critical, the message is transmitted via interphone (Service F). Any subsequent change or cancellation to the proposed flight plan message must be called to the ARTCC via interphone.

IFR Flight Plan Message

The IFR flight plan message consists of the following items, all of which are from the filed DD-175 with the exception of items 1 through 4:

1. The 3-letter identifier of the ARTCC.

2. The 3-letter identifier of the originating station and four figures to indicate the time the flight plan was received by the station.

3. Three figures to indicate the number of the message. This number sequence begins with 100 each day at the time specified by the ARTCC.

4. The alphabetical character N. (All proposed IFR flight plan messages must contain this character.)

NOTE: Items 1 through 4 are required on teletype only.

5. Aircraft identification.

6. Type aircraft/special equipment suffix.

7. True airspeed.

8. Departure point.

9. Proposed departure time.

10. Altitude.

11. Departure point and route of flight. The route of flight must include the departure point, since it may be different from the station transmitting the message; the route of flight to the next fix; the identifier of that fix and route of flight to the next fix; and so on until destination which is the last part of this item. (See example.)

12. Remarks.

ARTCC's will acknowledge all movement messages on Military B and Area B circuits except domestic proposed IFR flight plan messages.

Examples of proposed IFR flight plan messages:

1. Teletype. . . .ZEM NQA 1315103NVV 71534C118/B 0180 NQA P1405 60 NQA MEM V16 DAL V16S NBE REQ RADEP.

10431

Figure 14-6.—Circuit controlled by positive counter.

Figure 14-7.—Negative counting circuit.

voltage of the applied signal as shown in figure 14-5. This voltage varies directly as the frequency of the applied signal varies; that is, the average voltage increases as frequency increases, and decreases as frequency decreases. A milliammeter is placed in series with the plate circuit of V3 so that changes in the average plate current of V3 are indicated as a measure of variations in the recurrence frequency of the input pulses.

It was stated earlier that the applied waveshape may vary only in frequency. Glance at figure 14-5. If the pulse width or amplitude of the applied signal varies, then the average current, and therefore the average voltage, through R1 varies. This circuit is intended to indicate changes in frequency by measuring the average voltage across R1, so frequency is the only variation that can be permitted. The applied pulses are first sent through limiting circuits to insure exact amplitude, and shaping circuits to insure exact pulse width.

This counting circuit is frequently found in radio altimeters.

NEGATIVE COUNTER

By reversing the connections to the diodes V1 and V2 in the positive counting circuit the device can be made to respond to negative pulses, and thus it becomes a negative counter circuit. This circuit is shown in figure 14-7. Diode V2 conducts during the time the negative pulse is applied and a current flows through R1 as indicated by the arrow. At the end of the negative pulse V1 conducts sufficiently to remove the small charge which developed on C1 during the pulse time. The current through R1 increases with an increase in the pulse frequency as before. However, if the voltage developed across R1 is applied to the same control tube shown previously, the increase in current causes the grid of V3 to become more negative. This decreases the plate current through V3 and the meter. Thus an increase in the frequency of the negative pulse causes a drop in the average plate current measured by the meter. This effect is the opposite to that in the positive counter.

STEP-BY-STEP COUNTER

The step-by-step counting circuit is similar to those already discussed except that a capacitor which is large compared to C1 replaces the resistor R1 used in the positive counting circuit. The charge on this capacitor, C2 (fig. 14-8) increases slightly during the time of each positive pulse and produces a step voltage across the output. These steps decrease in size exponentially as the voltage across C2 approaches the final value, the rate being dependent upon the output impedance of the driving circuit. As long as there is no path through which C2 can discharge, the voltage across it continues to increase with each successive pulse until it is approximately equal to the amplitude of the applied signals. At this point the cathode of V2 is held at a positive voltage equal to that on the plate during the pulse time and the tube fails to conduct. Note that the charge on C2 eventually approaches 100 volts, the peak-to-peak value of the applied signal. This is caused by the charge on C1 being in series aiding with the input voltage during the negative half cycle of input.

Circuit Action and Waveshape Analysis

Use is made of the step charging circuit to trigger a blocked oscillator after a certain number of steps. A simple circuit of this type

1040

Flight Progress Strips

Flight progress strips are used to post current data on air traffic and clearances required for air traffic control and air traffic services. Terminal facilities providing approach control service must use the flight progress strips as listed in FAA manual AT P 7230.1 (Series), section 500. At some locations these strips are also used in the tower and flight clearance offices for recording data in a manner prescribed locally.

Figure 3-4 shows a departure and arrival flight progress strip with each box numbered for the purpose of explaining each part.

The following numbered items are appropriate entries in the correspondingly numbered boxes on the departure strip in figure 3-4.

1. Aircraft identification.
2. Type aircraft/special equipment suffix.
3. Computer identification number, if required.
4. Proposed altitude.
5. Proposed departure time.
6. Radar beacon (SIF) code assigned.
7. Departure point, route, destination, remarks, and/or clearance information.
8. Actual departure time.
9. Runway used for takeoff and departure point, if required.
10. (√) After clearance has been issued to the pilot.
11. (√) After clearance has been issued to terminal radar control (TRACON) for relay to the pilot.
12. (√) After actual departure time has been forwarded to the ARTCC.
13. Assumed departure time.

The following numbered items are appropriate entries in the correspondingly numbered boxes on the arrival strip in figure 3-4:

1. Aircraft identification.
2. Type aircraft/special equipment suffix.
3. Computer identification number, if required.
4. Radar beacon (SIF) code assignment.
5. Handoff or transfer of control point.
6. Clearance limit.
7. Destination airport.
8. ETA at clearance limit. The four digits of the hours and minutes should be used for the first entry. Subsequent entries may be only the two digits of the minutes, if desired.
9. Actual time of arrival (ATA) at clearance limit, if required.
10. Altitude in hundreds of feet.

11 through 20 are not standardized and may be used as determined by local authority.

Recording Flight Data

Only authorized control information symbols, abbreviations, and phrase contractions should be used for recording position reports, air traffic clearances, and instructions on flight progress

DEPARTURE STRIP

ARRIVAL STRIP

AC.7

Figure 3-4.—Flight progress strips.

10432

strips. Plain language, abbreviations or contractions contained in FAA Contractions Handbook 7340.1 (Series), and control information symbols contained in FAA Handbook 7110.8 (Series) must be used as necessary so that any written message may be read and understood.

The following list includes approved prefixes used in conjunction with the serial number to identify the branch of military service to which the aircraft is attached. These prefixes are appropriate for use in box number 1 on both the departure and arrival flight progress strips.

Prefix	Branch
A	U.S. Air Force
C	U.S. Coast Guard
G	Army or Air National Guard
VM	U.S. Marine Corps
R	U.S. Army
VV	U.S. Navy
CAF	Canadian Force
CAM	Canadian Armed Force Transport Command

The following list includes approved military mission prefixes which may be used with or in place of the prefix indicating branch of service that may be used in conjunction with the aircraft serial number. These prefixes are appropriate for use in box number 1 on both the arrival and departure flight progress strips.

Prefix	Mission
E	Medical Air Evacuation
H	Hurricane Evacuation
L	LOGAIR (USAF Contract)
S	Special Air Mission
T	MAC (Military Airlift Command)
F	Ferry Flight

The following list is approved aircraft equipment suffixes to indicate that an aircraft has transponder or TACAN-only navigational capability. These suffixes are used following a slant mark (/) after the aircraft type. They are appropriate for use in box number 2 on both the departure and arrival flight progress strips.

Suffix	Meaning
/X	Transponder with no-code capability.
/T	Transponder with 64-code capability.
/U	Transponder with 4096-code capability.
/D	DME
/L	DME, and transponder with no-code capability.
/B	DME, and transponder with 64-code capability.
/A	DME, and transponder with 4096-code capability.
/M	TACAN-only, and transponder with no-code capability.
/N	TACAN-only, and transponder with 64-code capability.
/P	TACAN-only, and transponder with 4096-code capability.

Figure 3-5 shows control information symbols used for recording clearances, instructions, and information on flight progress strips. Some of the symbols can be used in various boxes on both the departure and arrival flight progress strip; however, the most consistent use of these symbols may be in box number 7 on the departure strip where the ATC clearance to be issued to the aircraft is recorded.

The following list includes approved clearance abbreviations used to record a particular clearance issued or to be relayed to an aircraft, or the status of a clearance. These abbreviations may be used in various boxes on both the departure and arrival flight progress strips.

Abbreviation	Meaning
A	Cleared to airport (point of intended landing).
B	Center clearance delivered.
C	ATC clears (when clearance relayed through a non-ATC facility).
D	Cleared to depart from the fix.
F	Cleared to the fix.
H	Cleared to hold and instructions issued.
L	Cleared to land.
N	Clearance not delivered

10433

Symbol	Meaning
↑ (Altitude)	CLIMB AND MAINTAIN (Altitude).
↓ (Altitude) (Time) (Fix)	CLIMB AND MAINTAIN (Altitude) AT (Time); or; AFTER PASSING (Fix).
→	CRUISE.
@	AT.
X	CROSS.
⊸	MAINTAIN.
≠	CROSS AIRWAYS.
⇒	JOIN OR INTERCEPT AIRWAYS, TRACK OR COURSE.
═	WHILE ON AIRWAYS.
△	WHILE IN CONTROL AREA.
↘△	ENTER CONTROL AREA.
△↗	OUT OF CONTROL AREA.
↘⊙	ENTER CONTROL ZONE.
⊙↗	OUT OF CONTROL ZONE.
⊖→	THROUGH CONTROL ZONE.
Ⓦ	WHILE IN CONTROL ZONE.
>	BEFORE.
<	AFTER.
T→	TAKEOFF (Direction, if specified).
( ) / Restriction	ALTERNATE INSTRUCTIONS. RESTRICTION.
↓	BELOW.
↑	ABOVE.
— (dash)	INDICATES FROM--TO: ROUTE OR ALTITUDE.
V<	CLEARANCE VOID AFTER (Time).

AC.8

Figure 3-5.—Control information symbols.

10434401

Symbol	Meaning
(V)	SPECIAL VFR CONDITIONS.
₵	PILOT CANCELLED FLIGHT PLAN.
✓	INFORMATION FORWARDED.
(NM) (DRCTN)	VIA (number of miles) MILE ARC (direction) OF (name of DME aid).
LAX 120.3	CONTACT (facility name) ON (Frequency).
/	UNTIL.
(50)	OTHER THAN ASSIGNED ALTITUDE REPORTED (circle reported altitude).
[10/6]	DME HOLDING (use with milages). (Upper figure indicates distance from station to DME fix, lower figure indicates length of holding pattern. In this example, the DME fix is 10 miles out with a 6 mile pattern indicated.)
R	RADAR CONTACT.
~~R~~	RADAR SERVICE TERMINATED.
~~X~~	RADAR CONTACT LOST.
(R)	RADAR HANDOFF (circle symbol when handoff completed).
RV	RADAR VECTOR.
~~RV~~	PILOT RESUMED OWN NAVIGATION.
W (red)	WARNING

NOTE: The absence of an airway or route number between two fixes in the route of flight indicates "direct"; no symbol or abbreviation is required.

Figure 3-5.—Control information symbols—Continued.

10435 32

Abbreviation	Meaning
O	Cleared to the outer marker.
Q	Cleared to fly (courses, quadrants, radials) within _____ miles from (location).
T	Cleared through (for landing and takeoff through intermediate point).
V	Cleared over the fix.
X	Cleared to cross (airway, route, radial) at (point).
Z	Cleared to tower jurisdiction.

The following listed miscellaneous abbreviations are used mostly by approach control; however, there are occasions when control tower operators make use of them.

Abbreviation	Meaning
C	Change to center frequency.
CT . . .	Contact approach.
I	Initial approach.
F	Final approach.
JP . . .	Jet penetration.
MA . . .	Missed approach.
SR . . .	Standard range approach.
SI	Straight-in approach.
TA . . .	TACAN approach.
LT . . .	Left turn.
RT . . .	Right turn.
VA . . .	Visual approach.
VR . . .	VOR approach.
FM . . .	Fan marker approach.
ILS. . . .	ILS approach.
LP	Left traffic pattern.
OTP . . .	VFR conditions on top.
PT	Procedure turn.
RX	Report crossing.
RP	Right traffic pattern.
SA	Surveillance approach.
PA	Precision approach.

Figure 3-6 shows the standard recording procedure for hand printed characters on flight progress strips.

ATC Clearances

With a proposed IFR flight plan on file, the AC on duty at the ground control position in the control tower, clearance delivery, or departure control position, as appropriate, will request an ATC clearance from the ARTCC when the pilot calls the tower for taxi instructions or requests his clearance. ATC clearances, advisories, or requests must be relayed verbatim.

The following is an example of an ATC clearance received via Service F from the ARTCC of the proposed IFR flight plan shown in figure 3-1.

ATC CLEARS NAVY SEVEN ONE FIVE THREE FOUR TO THE NAVY DALLAS AIRPORT VIA VICTOR SIXTEEN DALLAS VICTOR SIXTEEN SOUTH NAVY DALLAS, MAINTAIN SIX THOUSAND, EXPECT VECTOR TO INTERCEPT VICTOR SIXTEEN, SQUAWK ONE ZERO ZERO ZERO ON DEPARTURE, MB.

Typed	Hand Printed	Typed	Hand Printed	Typed	Hand Printed	Typed	Hand Printed
A	A	J	J	S	S	1	1
B	B	K	K	T	T	2	2
C	C	L	L	U	U	3	3
D	D	M	M	V	V	4	4
E	E	N	N	W	W	5	5
F	F	O	O	X	X	6	6
G	G	P	P	Y	Y	7	7
H	H	Q	Q	Z	Z	8	8
I	I	R	R	Ø	*Ø	9	9

*Placing a slash through the number zero is not required in the hand printing of altitude or time entries on all flight progress strips.

AC.10

Figure 3-6.—Recording of hand printed characters.

10436

Figure 3-7 is a completed flight progress departure strip on which the clearance is recorded using appropriate symbols and contractions.

IFR Departure Reports

Immediately after an IFR flight is airborne, a departure report must be sent via interphone (Service F) to the control facility with which the flight plan was filed. The departure report must contain the aircraft identification and the actual time of departure.

IFR Flight Progress Reports

IFR flight progress reports consisting of the aircraft identification, position, time, altitude or flight level, estimate of the next reporting point, name of the subsequent reporting point, and any remarks or requests as received from a pilot must be relayed to the appropriate ATC facility via interphone (Service F).

IFR Arrival Reports

The actual time that an IFR flight lands or cancels the IFR flight plan must be relayed to the appropriate ATC facility via interphone (Service F).

Flight Service for IFR Flights

All procedures and reports as discussed earlier in this chapter for handling VFR flights apply to IFR flights as well. The exchange of information between base operations and the ARTCC is additional flight plan handling procedure required for the purpose of providing separation between aircraft operating IFR. In many instances certain reports must be sent to both Flight Service and the ARTCC.

COMBINATION IFR/VFR FLIGHTS

Pilots may file flight plans containing both VFR and IFR operations. Such flight plans are handled in the same manner as regular VFR or IFR flight plans except that the proposed IFR flight plan message is sent to the ARTCC in whose area of responsibility the aircraft changes from VFR to IFR.

If the first portions of such flights are IFR, or the change from VFR to IFR occurs at a position within the ARTCC's area within which the departure airport is located, the proposed flight plan message may be sent via Military B teletype or Service F by base operations at the departure airport. If the first portion is VFR and subsequent portions are IFR in a different ARTCC's area, the proposed flight plan message would probably be sent via interphone to Flight Service for transmission on Area B teletype to the ARTCC in whose area the change from VFR to IFR occurs.

SAR PROCEDURE FOR IFR AIRCRAFT

ARTCC's are responsible for assuring that SAR procedures are initiated for overdue IFR aircraft. ARTCC's serve as the central point for collecting information, coordinating with ARC, and conducting a communications search for overdue or missing IFR flights.

For SAR purposes, ARTCC's consider combination VFR/IFR flights and air filed IFR flights the same as IFR aircraft when 30 minutes have elapsed since the pilot requested clearance and radio communication or radar contact cannot be established.

An IFR aircraft is considered overdue when neither radio communication nor radar contact can be established with it and 30 minutes have elapsed since an ETA over a specified or compulsory reporting point or clearance limit.

AC.11

Figure 3-7.—Completed flight progress departure strip.

Overdue Action

The ARTCC in whose area of responsibility an IFR aircraft is first unreported or overdue is responsible for making this determination and initiating the necessary action. When an IFR aircraft is determined overdue, the appropriate ARTCC must alert the associated RCC and transmit an ALNOT.

The ALNOT is sent to all ARTCC's and Area B circuits 50 miles on both sides of the route of flight from the last reported position to destination. Included in the ALNOT is the original or amended flight plan, as appropriate, and the last known position. At the recommendation of the RCC or at the discretion of issuing ARTCC, the ALNOT search area may be expanded to cover the maximum range of the aircraft.

The responsibility for further search is transferred to the RCC under any of the following conditions:

1. When 30 minutes have elapsed after the estimated fuel exhaustion time.
2. When the aircraft has not been found within 1 hour after issuing the ALNOT.
3. When the ALNOT search has been completed with negative results.

The ALNOT remains in effect until the aircraft is found or the search is abandoned by the RCC, at which time it must be cancelled by the originating ARTCC.

Handling procedure for stations receiving the ALNOT, including broadcasting the ALNOT, are the same as those listed under SAR procedure for VFR aircraft.

Restriction to Other IFR Traffic

Unless radar separation is applied, when an IFR aircraft is unreported, the facility responsible must restrict or suspend other IFR traffic for 30 minutes after whichever of the following is applicable:

1. The time at which approach clearance was delivered to the pilot.
2. The expected approach clearance time delivered to the pilot.
3. The arrival time over the navaid serving the destination airport.
4. The current estimate, either the control facility's or the pilot's (whichever is later), at the navaid serving the destination airport.

After the 30-minute traffic suspension period has expired, normal air traffic control may be resumed if the operators or pilots of other aircraft concur.

RADIO COMMUNICATIONS FAILURE

When an IFR aircraft experiences two-way radio communications failure, air traffic control is based on anticipated pilot action. Pilot procedures are set forth in FAR 91.127 listed in chapter 9 of this Rate Training Manual. ATC facilities should take the following action, as appropriate, when two-way radio communications are lost with an IFR aircraft:

1. Broadcast clearances through any available means of communication, including the voice feature of navaids.
2. Attempt to reestablish communications by having the aircraft use its transponder (SIF) or make turns, both of which might be considered an acknowledgment when observed on radar.
3. Broadcast a clearance for the aircraft to proceed to its filed alternate airport at the minimum en route altitude if the aircraft operator concurs.

FLIGHT ADVISORY MESSAGES

If hazardous conditions arise which might affect an aircraft already in flight, it may be necessary to issue a flight advisory message to make sure the pilot is aware of the situation.

If a military aircraft's destination is a civil airport, the destination FSS is responsible for screening weather, airport, and navaid conditions, and issuing the necessary advisory to inbound aircraft. If the destination is a military base, the responsibility rests with base operations.

The tie-in station originating the advisory or receiving it from the originating base operations will determine the FSS nearest the aircraft's position for VFR flights or the appropriate ARTCC for IFR flight, and transmit the message to that location.

If the receiving FSS or ARTCC is unable to deliver the flight advisory to the aircraft within 15 minutes after the requested delivery time, the originator must be informed and then the message is filed.

MILITARY OVERSEAS FLIGHT SAFETY MESSAGES

Overseas flights are required to file through specific military based with clearing authority for such flights. Base operations at such locations forward an IFR flight notification message to the appropriate ARTCC. When an aircraft

10438

departs, base operations must also forward an ICAO DEP PLN (International Civil Aviation Organization flight plan including the actual time of departure) via the tie-in FSS to the appropriate International Flight Service Station (IFSS) for relay to the overseas addressees. FAA IFSS's are located at New York, Miami, and San Francisco to handle international communications in their respective areas.

For outbound flights the departure tie-in FSS holds the DEP PLN in suspense until an arrival or acknowledgment message is received from the destination base.

For inbound flights the relaying IFSS holds the DEP PLN in suspense until an arrival or acknowledgment message from the destination tie-in FSS has been forwarded to the departure base.

CIVIL NOTICE TO AIRMEN

A Notice to Airmen is a notice identified either as a NOTAM or Airmen Advisory containing information concerning the establishment, condition, or change to any component of, or hazard in, the National Airspace System, the timely knowledge of which is essential to personnel concerned with flight operations.

A NOTAM is a Notice to Airmen in message form requiring expeditious and wide dessemination by telecommunications means.

An Airmen Advisory (AIRAD) is a Notice to Airmen normally only given local dissemination, during preflight or in-flight briefing, or otherwise during contact with pilots.

Civil NOTAM's are transmitted by teletype when the basic flight publications do not contain current information concerning the following:

1. A landing area condition which precludes safe operation of aircraft.
2. An unscheduled change in, or irregular operation of, any component of the national airspace system which precludes the use of a facility for normal aircraft operations.
3. Any scheduled and published change to components of the national airspace system that is rescheduled or modified.
4. New or modified instrument procedures or changes in operating minimums.

NOTAM CODE

The NOTAM code provides for coding NOTAM information to reduce telecommunications transmission time and reduce translation difficulties in the International Service.

A NOTAM code group contains 5 letters. The first letter is always the letter Q to indicate a code abbreviation for use in the composition of NOTAM's. The letter Q has been chosen to avoid conflict with any assigned radio call sign.

Five-letter NOTAM code groups are formed in the following manner:

1. First Letter. The letter Q.
2. Second and Third Letters. The appropriate combination of two letters, selected from the "2nd and 3rd letters" section of the code, identifies the facility, service, or danger to aircraft in flight being reported upon. The second letter has been restricted to A, E, I, O, or U. These letters also serve to classify the aid, facility, or service described; i.e., the letters A and E signify radio aids. The letter I signifies lighting facilities. The letters O and U signify airports, search and rescue, and dangers to aircraft in flight.
3. Fourth and Fifth Letters. The appropriate combination of two letters, selected from the "4th and 5th letters" section, denote the operating status of the facility, service, or danger to aircraft being reported upon. The fourth letter has been restricted to A, E, I, O, or U.

Figure 3-8 shows some examples of how the NOTAM code group is assembled along with the meaning of each.

The example below shows a NOTAM transmitted by NAAS Fallon:

→ NFL 4/2 QANOG

Decoded, the NOTAM has the following meaning: The west arrow is an automatic data processing code for Service A, the transmitting station (NFL) is NAAS Fallon, the NOTAM is the second issue since the beginning of the fourth month, and the Fallon TACAN is operative but ground checked only, awaiting flight check.

The complete NOTAM code is found in several publications including the Airman's Information Manual, FLIP Planning, and Flight Service Handbook 7110.10 (Series).

Navy NOTAM's are handled mainly on the USAF Comet teletype system; however, by prior local arrangement, a military facility having a send-receive capability on Service A is authorized to transmit NOTAM's in accordance with

10439

2nd & 3rd letters	Meaning	2nd & 3rd letters	Meaning
AN	TACAN.	IH	Taxiway lights.
EE	Ground Controlled Approach System (GCA).	OA	Land aerodrome.
EK	Precision Approach Radar (PAR).	UT	Grass landing area.

4th & 5th letters	Meaning	4th & 5th letters	Meaning
AE	Totally free of snow and ice.	OK	Resumed normal operation.
EM	Military operations only.	OG	Operative but ground checked only, awaiting flight check.
IF	Flight checked and found reliable.	UF	Closed for an unknown duration due to flood.

AC.12

Figure 3-8.—NOTAM code example.

FAA procedure (Flight Service Handbook 7110.10 (Series)). NOTAM coverage on Service A includes a daily summary of NOTAM's transmitted at approximately 0800Z.

USAF/USN NOTAM SYSTEM

The USAF/USN NOTAM system was established to provide for rapid dissemination of Navy, Air Force, and selected civil NOTAM's in plain language to USAF and USN air activities, and provide for frequent, periodic summaries of current NOTAM's.

This system is centrally coordinated and operated by the USAF Central NOTAM Facility (CNF). The USAF CONUS Meteorological Teletype System (COMET) is used for the transmission of these NOTAM's. Navy and Marine Corps air facilities in the counterminous U.S. have transmit and/or receive capabilities on the COMET system.

Central NOTAM facilities are also established at certain overseas locations for the purpose of exchange of Navy and Air Force NOTAM's within each area, and between each area and the U.S. NOTAM's in these systems are transmitted over existing administrative and operational circuits.

NOTAM RESPONSIBILITY

The responsibility for originating a NOTAM rests with the commanding officer having jurisdiction over a facility where a hazardous condition exists or is contemplated. This responsibility includes insuring that NOTAM dissemination

is adequate and timely, and that NOTAM's are promptly canceled.

Additionally, the commanding officer (clearing authority) is responsible for the promulgation of all NOTAM's received. This responsibility includes, but is not limited to, conspicuous posting within flight planning areas, and dissemination to local units within their area of jurisdiction.

The Naval Oceanographic Office (NAVOCEANO) monitors Navy NOTAM's to insure compliance with the appropriate instructions governing NOTAM procedure.

Each activity concerned with the issuance of NOTAM's must implement standard procedures to assist appropriate duty personnel in the correct preparation, transmission, and display of NOTAM's.

Originators of NOTAM's must insure the following:

1. Adequate on-station procedures to provide rapid reporting of navaid malfunctions that affect the operation of the station, regardless of the operating agency of the facility concerned.
2. Standardized station procedures for the preparation of each NOTAM in accordance with the requirements for the particular circuit on which it is to be transmitted. The NOTAM is normally prepared by ATC personnel.
3. Each item is carefully phrased and identified as a separate NOTAM, and the same accountability identifier is used in any revisions to or cancellation of the NOTAM.
4. Dissemination on appropriate circuits to civil and military activities concerned.
5. Followup of station orginated NOTAM's to provide for prompt and accurate publication, revision, and cancellation as soon as the condition is rectified or published in FLIP's.
6. Forwarding to the NAVOCEANO any amplifying data necessary for permanent or semipermanent changes to the appropriate FLIP's.

HOW TO PREPARE A USAF/USN NOTAM

NOTAM Format

Each NOTAM is identified by its date and accountability number; for example, 020311397, which is broken down as shown in figure 3-9.

Once this number is assigned, it must be used to refer to the NOTAM for all purposes, including revision, extension, and cancellation. The accountability number is always composed of five digits. The first two digits are assigned consecutively by the initiating base and begin with "01" each month, as computed from Greenwich Time. The CNF uses this portion of the number to verify that it has received all NOTAM's from the respective bases. The last three digits are assigned consecutively by CNF, and run from "001" to "999." This portion of the number provides a means for each receiving point to insure that it has received all NOTAM's retransmitted by the CNF.

Use of Clear Text, Code, or FLIP Abbreviations

If the NOTAM is being transmitted within CONUS or within the USAF Communications System, it is sent in clear text. If the NOTAM is being transmitted via a designated ICAO communications circuit, it is sent in the appropriate five element "Q" code as described earlier in this chapter.

Self-Canceling NOTAM

This is prepared in the same format as a new NOTAM, except that it shows when the NOTAM becomes effective and when it expires. (See date-time groups in fig. 3-10.) Such a NOTAM does not require canceling, because it has a date and time indicating when it expires.

Cancellation NOTAM

Each NOTAM that cancels a current NOTAM must use the letter "C" instead of the letter "N," and must repeat the same accountability number that was assigned to the NOTAM it cancels. The cancellation NOTAM must tell the present condition of the facility. (See example in fig. 3-11.) When a NOTAM has caused information to be added to or removed from FLIP, a cancellation NOTAM is sent, if appropriate, after the removal/addition is made. (The appropriate FLIP is consulted to determine whether the information has already been corrected.)

Revised NOTAM

This NOTAM is sent to revise or correct a current NOTAM. The letter "R" is used preceding the accountability number, and the same accountability number as the NOTAM being

01 10441

*NOTE: The serial number added on the end of a "C" NOTAM is added by CNF for the purpose of numerical sequence since the original accountability number is used on this type NOTAM and is of no significance to the sender or user.

AC.15

Figure 3-11.—Cancellation NOTAM.

revised or corrected is used. (See how this is indicated in fig. 3-12.)

NOTAM SERVICES FURNISHED

The USAF/USN NOTAM system provides CONUS dissemination of each NOTAM at the time it is initiated, and a twice-daily summary designated NOTAM Summary Part I. This summary consists of those NOTAM's outstanding at 0900Z and 2100Z daily which are judged to be of temporary duration. This summary is alphabetically arranged, and can be removed from the teletypewriter in sheet form for NOTAM Display Board posting. It is intended to be continuously updated from individually issued NOTAM's until replaced by a new Part I Summary.

A weekly summary, designated NOTAM Summary Part II, is issued containing those NOTAM's which are judged to be of indefinite duration, or NOTAM's involving specific corrections to the FLIP's. The CONUS Part II NOTAM Summary is normally compiled as of 0900Z each Saturday, and is intended to be retained on the NOTAM Display Board until replaced by a new Part II Summary. This should be updated from the Part II NOTAM additions and deletions which are issued twice daily.

The USAF/USN NOTAM system provides the Europe and Pacific areas with individually issued NOTAM's, a daily Part I Summary, and a weekly Part II Summary, with daily additions and deletions to each. The system also provides for a daily exchange, between areas, of NOTAM Summaries containing selected coverage based on operational requirements.

NOTAM DISPLAY BOARD POSTING

Each activity must maintain a standard NOTAM Display Board in the flight planning area in accordance with the procedure outlined in OpNav Instruction 3710.7 (Series). Standard display procedure must be implemented at each activity to assist AC's on duty in maintaining the NOTAM display including the following:

NOTAM R 290114437 KRAN 2468 RAN TACAN OUT (REMARKS)

AC.16

Figure 3-12.—Revised NOTAM.

1. Adequate procedures for the receipt, on-station dissemination, and posting of incoming terminal, en route, and special NOTAM's from appropriate circuits.

2. Constantly updating the display and removing obsolete information at least once each hour, or more often.

3. Checking new Summaries for completeness before destroying old Summaries.

4. Monitoring NOTAM's and NOTAM Summaries, and new editions of FLIP's, to insure that they reflect current conditions for their station, and initiate corrective NOTAM's on any deficiencies.

5. Decoding ICAO coded NOTAM's and identifiers to plain language before posting.

6. Availability of sufficiently knowledgeable personnel to assist the pilot in checking NOTAM information.

For more detailed study and information concerning NOTAM's, the AC should refer to OpNav Instruction 2112.2 (Series), Air Force Manual 55-13, and OpNav Instruction 3710.7 (Series).

10444

CHAPTER 4

CONTROL TOWER EQUIPMENT

The purpose of this chapter is to introduce the Air Controlman to the various types and pieces of equipment found in control towers throughout the Navy. Great strides have been taken in the past decade to standardize and modernize both the control towers and the equipment therein. Through constant research and development, the Air Controlman, may expect to see even more development in equipment in the future. This is necessary to keep pace with the rapid progress being made in the field of aviation.

The equipment and methods of operation discussed in this chapter are considered to be most widely in use at this time. As new methods and equipment are installed at duty stations, it behooves every Air Controlman to study diligently, not only the method of operation, but the capabilities and limitations of the equipment and the techniques utilized.

JOINT ELECTRONICS TYPE DESIGNATION SYSTEM

The Joint Electronics Type Designation System (JETDS), formerly known as the AN nomenclature system, was developed to standardize, within the DOD, identification of electronic material and associated equipment.

This system of type designations applies to developmental, preproduction, and production models of systems, groups, components, and subassemblies of electronic equipment for military use. Once assigned, a type designation will never be duplicated. In the JETDS, nomenclature consists of a name followed by a type designation, which is composed of indicator letters and an assigned number. The type designation will always apply to one specific article or any subsequent improvements that may be made on that article.

A type designation assignment for a complete system, or set, consists of an AN (which is used to identify major items of electronic equipment), a slant bar, a series of three letters, a hyphen, and a number. The meanings of the three letters following the slant bar may be found in the table included in this manual as appendix II.

An example of a type designator would be Radar Set AN/SPS-10, which is a search radar set designed for installation aboard ship.

COMMUNICATIONS CONSOLES

Radio is the primary means of communications with aircraft, both in the air and on the ground. Different radiofrequencies are established for a particular type of operation. For example, most Navy towers have 340.2, 360.2, 142.74, and 126.2 assigned specifically for airport traffic control purposes. Additional frequencies may be established by appropriate authority at some facilities depending upon operational requirements. Different operating positions within the same facility may have to share the same frequency for a single aircraft operation. For example, single piloted IFR aircraft should be provided a single frequency approach to the maximum extent that communications and traffic conditions permit. Therefore, approach control, radar facility, and the control tower may find it necessary to use the same frequency sometime during such an operation. Additionally, interfacility communications may be necessary for coordination between the different operating positions where physical contact between controllers is not possible. To provide controllers with this capability, communications consoles are provided which allow selection of various frequencies and intercommunications between operating positions.

10445 42

AN/FRA-11 COMMUNICATIONS CONSOLE

The AN/FRA-11 is a communications control system designed to provide unified air-to-ground voice communications. Facilities incorporated in the equipment provide flexible control of sixteen transmit/receive communications channels. The transmitters and receivers may be either locally or remotely located. The system is comprised of three operating positions designated as control indicators A, B, and C, and four equipment racks containing the associated control equipment. The three control indicators are installed in the control tower and are normally separated while the equipment racks are installed in the equipment room below the tower.

The control monitor indicators are identical except that indicator A has a control common to all three indicators for controlling the intensity of the indicating lamps.

Radiotelephone messages from aircraft received by any one of the sixteen radio receivers can be heard by operating personnel through the overhead speakers, pulldown speakers, or headsets. Each radio receiving channel has an identification lamp which is automatically illuminated when the channel is in use. Sixteen lever type switches provide the operator with a means of setting the overhead speaker output level for any channel to HI-LO-OFF. A second row of lever type switches permits the operator to select any radio signal and feed it to the pulldown speaker. (See fig. 4-1.) Regardless of the position of the receiver selector switches, the receiver indicator lamps will light when the signals are received.

The sixteen transmitters may be operated from any one of the three control indicators by the level type switches located on the transmitter control panel of the control indicators. When an operator desires to transmit, the lever type switch is operated to the ON position. This causes the green STANDBY lamp to light, then the push-to-talk button on the microphone is depressed, the red BUSY lamp will light and the transmission is made. When the press-to-talk button of the microphone is released, the red BUSY lamp is extinguished. When the channel selector switch is returned to the OFF position, the green STANDBY light is also extinguished. If the operator at any position is using any particular channel, he is protected against having either of the other two operators interrupt his transmission through a system of interlocking relays. The other two operators have visual indication that the channel is in use since their respective BUSY lamps are lighted. However, if either of the operators should try to use the channel, a buzzer gives an audible indication that the channel is in use. Should an operator ignore the light and buzzer the interlocking relays prevent any interruption.

Although the AN/FRA-11 is still in use at many Navy facilities it is being replaced by newer equipment with additional features to satisfy the expanding needs of air traffic control communications.

AN/FSA-17 COMMUNICATIONS CONSOLE

The AN/FSA-17 communications console (fig. 4-2) is a communications control system for air traffic control centers at naval air stations and other facilities where several operators must exercise control over multichannel radio communications while at the same time maintaining interphone communications with each other.

The system provides control of as many as 20 transmitters with a lockout feature that denies the use of a transmitter to any other operator once selected. It also monitors as many as 20 radio receivers at any one time. An operator can talk to one or more other operators on the interphone feature. The interphone feature allows private line or party line intercommunication.

The operation of the console is simple, once the confusion of the multiplicity of controls is overcome. (See fig. 4-2.) Located on the right side of the console is a microphone level indicating meter, level controls for the microphone and headphone, and a dimmer control for illuminations, as well as lights and switches. The 3-position radiophone switches (fig. 4-2) control the receivers and transmitters. These switches are off in the down position. To monitor a frequency the switch is moved to the middle position. To select a transmitter, while monitoring the frequency, the switch is moved to the top position. The radiophone frequency chart (fig. 4-2) is a removable strip of translucent plastic placed below the radiophone switches. The frequency controlled by each switch may be written on this chart for ready reference. Above each switch is an amber light which glows when a

AC. 214

Figure 4-1. —AN/FRA-11 communications console.

radio call is received, regardless of the position of the switch. A green light immediately above each amber light will glow when a transmitter is selected by a corresponding switch.

The 20 interphone switches on the bottom of the console control the 20 private line interphone circuits. The switches are off in the down (middle) position. To call and talk to another operator, the switch corresponding to the desired operator is moved to the upper position. Above each interphone switch is a red light which will glow when the position is called by another operator (the one corresponding to the number under the light). The supervisor interphone switch provides a private line interphone circuit to the supervisor's console in the same manner as the other interphone switches.

The party line cutout enables a controller to disconnect from a party line (programmed into the system) by moving the switch up.

AC. 17

Figure 4-2. —AN/FSA-17 communications console.

A speaker amplifier control is supplementary equipment added to the control tower operator's console. (See fig. 4-3.) This unit is usually installed directly above the basic FSA-17 with corresponding frequencies. Placing any one of the 20 receiver switches on the speaker amplifier control removes that particular receiver from the operator's headphone circuit and feeds it to an associated speaker. The speaker level control provides for control of speaker volume. The dimmer control is used to adjust panel illumination intensity. The speaker muting system prevents acoustical feedback through a microphone. To achieve headphone operation on all frequencies, the operator needs merely to raise the muting switch.

Other auxiliary equipment necessary for controller operation such as headphone, etc., is the same as that shown in figure 4-4.

AN/FSA-52 COMMUNICATIONS CONSOLE

The AN/FSA-52 communications console is similar in design and basically the same in operation as the AN/FSA-17. It is newer equipment and allows for additional frequencies, intercommunication, and possible operating positions. It also may be programmed for the use of several direct telephone lines through the console. (See fig. 4-4.) A speaker amplifier control unit as shown in figure 3-3 is also used with the control tower AN/FSA-52 console. Other auxiliary equipment necessary for controller operation is shown in figure 4-4.

The AN/FSA-17 or AN/FSA-52 is the communications console used in Radar Air Traffic Control Centers (RATCC's). An illustration of the position of the consoles associated with a

10448

Figure 4-3.—Speaker amplifier control.

AC. 19

Figure 4-4.—AN/FSA-52 communications console.

10449

particular radar operating position is included in chapter 13 of this training manual.

Figure 4-5 shows a closeup of an actual installation of an AN/FSA-52 with the speaker amplifier control directly above it. Figure 4-6 shows the installation of the same communications equipment at three operating positions in a control tower. Additionally, some items of equipment discussed later in this chapter are shown in figure 4-6.

MICROPHONES

A microphone is essentially an energy converter that changes sound energy into corresponding electrical energy. When one speaks into a microphone, the audio pressure waves strike the diaphragm of the microphone and cause it to move in and out in accordance with the instantaneous pressure delivered to it. The diaphragm is attached to a device that causes current to flow in proportion to the instantaneous pressure applied to the diaphragm.

TECHNIQUES

Proper microphone technique is a necessity for all Air Controlmen in radiotelephone communications.

MICROCOPY RESOLUTION TEST CHART

NATIONAL BUREAU OF STANDARDS-1963-A

Figure 14-9.—Triggering blocked oscillator with step-charging circuit.

The first input pulse ends, C1 is discharged, but C2 holds its 10-volt charge. The second pulse occurs. The 10-volt charge on C2 opposes the 100 volts of the second pulse, and the total applied voltages to which the capacitors can charge is then 90 volts. E_a is 90 volts, and from the previous equation, C2 is again charged by 10 percent or 9 volts. This is in addition to the initial 10 volts, so at the end of the second pulse, the C2 voltage is 10 plus 9 or 19 volts. The third pulse is 100 volts again, but 19 volts oppose it. Therefore, Ea is 100 minus 19 or 81-volts and C2 charges and additional 8.1 volts. The new E_2 becomes 19 plus 8.1 or 27.1 volts. Successive input pulses raise C2 by 10 percent of the remaining voltage toward plus 100 until the blocked oscillator is actuated.

In the oscillator, the cathode voltage is set at plus 50 volts. The plate supply voltage is 250 volts, so the plate-to-cathode voltage is 200 volts. Using the plate-to-cathode voltage, you can determine the grid voltage for cutoff. From the curves in figure 14-9, this value is near minus 12 volts, as indicated on the characteristic curves. With the cathode at plus

1042

1401

AC. 21

Figure 4-6. —Control tower equipment.

In radiotelephone communications, the operator of the equipment becomes part of the system. The manner in which the message is delivered determines the effectiveness of the transmitted signal as well as the power and efficiency of the equipment.

The two general types of microphones used by AC's are the hand held type and the boom or headset type. Both types should be placed directly in front of the mouth, within one-half inch or almost touching the lips. Most microphones are relatively inefficient and the slightest variation of microphone position can drastically reduce the intelligibility of the message being transmitted. Figures 4-7 and 4-8 illustrate correct technique for hand held and boom or headset type microphones respectively.

VOICE RECORDER-REPRODUCER RD-217/UNH

The purpose of the RD-217/UNH (Sound-Scriber Model S-124) Single Channel Recorder/Reproducer is to record conversation between air traffic control facilities and aircraft. Recordings made of these conversations are used for aircraft accident analysis; circuit discipline; adequacy and accuracy of air traffic control facility instructions; immediate playback for as-

10451 Ot.P01

AC. 22
Figure 4-7.—Hand microphone technique.

sistance in search and rescue; and for voice training of air traffic control personnel.

OPERATION AND CONTROL

The description given here on the Recorder-Reproducer RD-217/UNH is brief. Supplement this description by studying the Sound-Scriber Service Manual sent with the recorder in order to familiarize yourself with the capabilities and limitations of the recorder.

The RD-217/UNH Single Channel Magnetic Tape Recorder-Reproducer has been engineered and designed to perform the specific task of continuously recording any desired communication signal over any period of time up to 24 hours without tape change. In addition, the time in minutes from 0000 to 1455 (24 hours, plus a 15-minute overtime allowance) has been precision printed on the visible side of the tape as it moves past the recording head.

All the controls of the magnetic tape recorder (except the automatic volume control switch) are conveniently located on the front panel. (See fig. 4-9.) Study the service manual for complete procedures as to the proper methods to follow when tapes are to be changed or when playback is desired.

The recording medium is a brown magnetic tape wound on a 3 3/4-inch diameter plastic reel with the coated side wound toward the inside. Each tape is 2 inches wide and approximately 312 feet long.

There are two time scales on each reel of tape. To permit easy location of recorded material, the uncoated side is stamped in minutes to provide a time scale. This scale starts at 0000 minutes at one end of the tape and is stamped along its length a total of 1,455 minutes. (See fig. 4-10.) The time scale that is right side up as the operator faces the recorder is the one being used. In order to locate a specific portion of the recording, it is necessary to convert the number to time. If the number is 0200, it indicates that 200 minutes have elapsed since the tape was actuated. The conversion formulas are: If you have the number, divide by 60; if you have the time in hours, multiply by 60 and add the minutes.

Recorded material can be stored under normal conditions for an indefinite period of time without magnetic deterioration. The ideal site for both the recorder and the spare tapes is a room where dust and dirt are at a minimum, the temperature ranges between 60° to 75° F, and the relative humidity is 60 percent or less. The tapes can be used over and over for recording by erasing the recorded material. To erase the recorded material, a demagnetizer is used.

AC. 24

Figure 4-9.—RD-217/UNH front panel controls.

The Chief of Naval Operations requires all air traffic control facilities to keep their recorded reels on file for a period of 10 days before erasing. However, in some instances a length of recorded material needs to be kept longer than the required time. In this case, the desired portion of the tape can be removed and another piece of tape the same length spliced in its place.

Each air traffic control facility has a maintenance kit supplied with each recorder. Within this kit are two reels of splicing tape. To splice the tape, place the ends of the tape that are to be spliced together, cut the tape at a 60-degree angle using a straightedge and razor blade or similar device and make sure that the cutting device is not magnetized. (See fig. 4-11.) Aline both ends of the tape with the uncoated side of the tape up and cover the alined ends of the tape with the splicing tape. The splicing tape should be allowed to protrude over the edges of the tape and should not be stretched, as stretching will cause it to curl. Apply pressure to the splicing tape with the thumbnail or a smooth object, then remove the excess tape with nonmagnetic scissors.

AC. 25

Figure 4-10.—Portion of magnetic tape.

DEMAGNETIZER

The demagnetizer is a portable unit contained in an aluminum cabinet. The demagnetizer is designed to erase the recorded material from a complete reel of tape. (See fig. 4-12 for an illustration and controls of the demagnetizer.)

To demagnetize a reel of tape, hold the power switch of the demagnetizer in the ON position until the neon light becomes bright, then place the reel of tape on the rollers. After the reel is placed on the rollers, rotate the reel three complete turns. After the turns are complete,

10453 S2P01

AC. 26

Figure 4-11.—Cutting magnetic tape.

slowly remove the reel from the demagnetizer and release the power switch. Be sure that the power switch is NOT released before removing the reel. If this is not done properly a loud swishing background noise will be heard when this reel is played back after is has been used for recording again. To complete this procedure of erasing, the tape should remain in the demagnetizer approximately 10 seconds, but in no case should it be left in the demagnetizer in excess of 15 seconds.

SAFETY PRECAUTIONS

Both the recorder and the demagnetizer employ voltages which are extremely dangerous if contacted by operating personnel. Operating personnel must at all times observe applicable safety regulations when using or working with this equipment. If the magnetic tape recorder is to be permanently located in one spot, ground chassis of machine to a good earth connection. Because of high voltage generated by the demagnetizer, it must be grounded. NEVER operate the demagnetizer without a proper ground. A very strong magnetic field is created by the two poles of the demagnetizer. Be careful not to place any delicate instrument close to this field.

WIND INDICATOR

Wind direction and wind velocity indicators are mounted in the control tower to provide controllers with first-hand wind information in order to select the proper runway to use during specified wind condition. They provide a method for prompt issuance of wind directions and velocities to pilots by controllers. Also, the controller may note a marked increase in velocity, gustiness, or a wind shift that if relayed immediately to the weather service personnel may be significant of impending or approaching weather changes. These instruments are of several sizes and mounted in various ways in the tower.

Normally the meteorological instruments located in the tower are "slaves" to the equipment in the meteorological office. The wind direction received in the weather office on the "master set" is "true" direction. On the other hand, the directional instruments in the tower must be compensated for magnetic variation so that the controller reads "magnetic wind," which is what he relays to the pilot.

Figure 4-13 illustrates the ID-586/UMQ-5 wind direction and speed indicator which is installed in many Navy control towers.

The wind indicator readings in the control tower must be compared with weather service readings at the beginning of each working day, keeping in mind that weather service direction is true and variation must be applied to obtain

AC. 27

Figure 4-12.—Demagnetizer.

10454 00101

AC. 28

Figure 4-13. —ID/586/UMQ-5 wind direction and speed indicator.

a correct reading. If the wind indicator is in error plus or minus 5 degrees in direction or 5 knots in speed, weather service maintenance personnel must be notified so that corrective action can be taken. If the instrument is in error over 10 degrees or 10 knots it is considered inoperative.

ALTIMETER SETTING INDICATOR

The altimeter setting indicator is a special form of aneroid barometer so designed that after installation and proper adjustment, the altimeter setting may be read directly from the scale of the instrument. (See fig. 4-14.) The instrument is designed to indicate the altimeter setting when the elevation scale is set to the actual elevation of the instrument above sea level. The mechanism is enclosed in a sealed case with provision for the connection of a venting tube leading to outside free air.

The altimeter setting indicator is the primary means of obtaining altimeter settings at terminal facilities. The altimeter setting indicator reading must be compared with the official altimeter setting of the weather service between 0800 and 0900 (local time) each day. If there is an error in the instrument of .02 but less than .04 inch, the correction factor is written on the face of the instrument for application to readings issued until weather service maintenance personnel can

AC. 29

Figure 4-14. —Altimeter setting indicator.

10455

check the instrument. If the error exceeds .04 inch, the instrument is considered inoperative. In both cases, maintenance personnel must be advised immediately. If the average windspeed is in excess of 40 knots at the time a correction factor is determined, the previously determined correction factor must be used until the average windspeed is less than 40 knots.

AC. 30

Figure 4-15.—Direction Finder Set AN/URD-4.

1045601

DIRECTION FINDER EQUIPMENT

Direction Finder Set AN/URD-4 functions as a means of determining rapidly the direction of fixed and mobile sources of radio transmissions. The equipment indicates the bearing of the transmission visually and delivers any associated audio signals to a headset upon connection of the headset to the equipment.

The direction finder set has a frequency range of 225.0 to 399.9 MHz in one band. Selection can be made of any one of 1,750 crystal-controlled channels. Any 20 of the 1,750 channels can be preset in order to allow for their rapid selection.

Inaccuracies in the visual bearing may occur as the result of reradiation from objects in the antenna vicinity. Operating personnel should acquaint themselves with distortions of the propeller-shaped pattern resulting from such reradiation. Preknowledge of such distortions will prevent misinterpretations of the visual pattern.

The equipment is immediately available for operation when IFR weather conditions exist during normal working hours of the station and on 5 minutes notice at all other times when the tower is manned.

Figure 4-15 illustrates the front panel of the URD-4 and lists the function of each control knob or switch.

OPERATING PROCEDURES

The AN/URD-4 found in naval control towers today is a valuable instrument to the Air Controlman. This direction finding equipment serves as

AC. 31

Figure 4-16.—Memory cylinder adjustment.

10457

an aid to aerial navigation; and when necessary, may be used as a standby receiver. The principal uses for navigational purposes are as follows: plotting the position of lost aircraft from the station, giving bearings to the aircraft from the station, and giving courses to the aircraft.

The basic operating procedures for the URD-4 are listed in the following paragraphs. Those numbers appearing in parentheses are referenced to the appropriate control knob or switch as illustrated in figure 4-15.

Channel Preselection

Twenty channels of the 1,750 channels available can be preset for rapid selection. Set up these 20 channels as follows:

1. Log the frequencies of the 20 desired channels on the frequency log chart (7) held in place on the indicator panel.
2. Push in the release pushbutton beside the switch and turn the RELease-LOCK switch (11) to RELease.
3. Grasp the channel selector switch (9) and pull the memory cylinder (fig. 4-16) straight out until it is free from the indicator control panel.
4. Hold the memory cylinder firmly with one hand, with the longitudinal slot up and the cylinder in a horizontal position, the panel facing the holder. Figure 4-16 illustrates the method of holding and setting the memory cylinder.
5. Rotate the channel selector switch to the desired channel position as indicated by the numbered dial on the front panel of the memory cylinder.
6. Place the first tab from the rear of the cylinder opposite the index digit marked on the cylinder case which corresponds to the first digit of the four-digit channel frequency being set up on the first preset channel.
7. Place the second tab from the rear of the cylinder opposite the index digit marked on the cylinder case which corresponds to the second digit of the four-digit channel frequency.
8. Place the third tab from the rear of the cylinder opposite the index digit marked of on the cylinder case which corresponds to the third digit of the four-digit channel frequency.
9. Place the fourth tab from the rear of the cylinder opposite the index marked on the cylinder case which corresponds to the fourth or decimal digit of the four-digit channel.
10. Set up the remaining channels as described in steps 5 to 9 inclusive.
11. Slide the memory cylinder back into place in the indicator. Turn RELease-LOCK switch to LOCK.

Energizing the Direction Finder Set

Energize the direction finder set as follows:

1. Throw POWER switch (15) to ON (fig. 4-15).
2. Throw MOTOR switch (1) to ON to start antenna rotation.
3. Turn LIGHTS switch (19) to give desired level of intensity for lamps on indicator panel.

Channel Selection

With the 20 channels preset, a choice can be made as to the mode of channel frequency selection—preset or manual. Procedures for the two modes are as follows:

1. Preset operation is as follows:
   a. Set MANual PRESET switch (12) to PRESET.
   b. Turn channel selector switch (9) to desired channel number. As the switch is turned, the desired channel number will appear under the arrow in the selector dial window, and the tuning mechanism will be activated.
   c. The amber lamp, TUNING (4), glows as the tuning mechanism seeks the channel. When the tuning mechanism comes to rest after finding the channel, the green lamp, ON CHANnel (5), glows.
   d. If the tuning mechanism cannot find the selected channel, due to malfunctioning of the mechanism or because the channel is out of the frequency range of the equipment, the red lamp, LOCKED (6), will glow, indicating that the tuning mechanism is locked. Depress RESET switch (16) momentarily to cause the tuning mechanism to unlock and recycle.
2. Manual operation is as follows:
   a. Set MANual PRESET switch (12) to MANual.
   b. Set digit selector switches (8, 10. 13, and 14) to the desired frequency.
   c. The amber lamp, TUNING (4), glows as the tuning mechanism seeks the channel. When the tuning mechanism comes to rest after finding the channel, the green lamp, ON CHANnel (5), glows.
   d. If the tuning mechanism cannot find the selected channel, due to malfunctioning of

10458

AC. 32

Figure 4-17.—DF pattern interpretation. (A) Calibrate pattern; (B) circular pattern; (C) DF bearing pattern; (D) DF sense pattern.

the mechanism or because the channel is out of the frequency range of the equipment, the red lamp, LOCKED (6), will glow, indicating that the tuning mechanism is locked. Depress RESET switch (16) momentarily to cause the tuning mechanism to unlock and recycle.

Calibration Pattern Check

Prior to use of the equipment for direction finding, check the calibration pattern as follows:

1. Throw CALIBRATE-SENSE switch (17) to CALIBRATE.
2. The tips of the 36 lobes of the calibration pattern should just touch the inside edge of the azimuth scale. (See fig. 4-17 (A).)
3. Lobes should be precisely at 360 degrees, 90 degrees, 180 degrees, and 270 degrees.
4. The converging point of the lobes should be at the intersection of the crossed lines of the cursor screen.
5. If the calibration pattern does not conform to requirements listed in steps 2 to 4 inclusive, have the equipment recalibrated by the electronic techniques.
6. Adjust the intensity of the calibration pattern with the aid of BRILLIANCE control (22, fig. 4-15). Adjust focus with FOCUS control (24).

Direction Finding Procedure

The direction finding procedure is as follows:

1. Throw CALIBRATE-SENSE switch (17) to center position; set RF GAIN control (18) near maximum.
2. Select the desired channel.
3. When no signal is being received, the cathode-ray tube displays a circular pattern. Random noise will distort the circular pattern if RF GAIN control is at or near maximum. (See fig. 4-17 (B).)
4. When a signal is received, the circular pattern is resolved into a propeller-shaped pattern, the tips of the propeller pointing along the bearing of the signal. (See fig. 4-17 (C).)
5. Rotate the cursor screen by means of the alidade operating ring (27) to line up the arrow etched in the screen along the axis of the bearing signal. The two lines parallel to the arrow facilitate alinement.
6. Throw CALIBRATE-SENSE switch (17) to SENSE. The propeller-shaped pattern will be transformed, the two lobes of the pattern bending back away from the direction of the signal origin. (See fig. 4-17 (D).)
7. The bearing of the signal can be read on the azimuth scale. Should the "sense" pattern indicate that the signal origin direction is opposite from the azimuth reading given by the cursor screen arrow, read the azimuth bearing at the tail end of the arrow.
8. Insert a headset into PHONES jack (26) if monitoring of the signal modulation is desired. Turn AF GAIN control (20) to the desired volume of audio signal level.

The operational procedures described here are only basic and should not be construed as being complete. Additional instruction and practice are necessary to fully understand the operational procedures used to obtain accurate, complete, and concise DF assistance.

When providing DF service to an aircraft in an emergency status, a controller should determine if the aircraft is in VFR or IFR weather conditions and the fuel remaining. If the aircraft is not on an IFR flight plan and is in VFR weather conditions, the pilot should be advised to remain VFR. If the aircraft is in IFR weather conditions, the pilot should be advised of the minimum safe DF altitude and coordination with the appropriate control facility must be effected. The appropriate DF net control should also be alerted.

NOTE: All stations are in a DF net which is an area determined geographically for the purpose of obtaining cross bearings from different stations to provide a fix.

The aircraft's approximate position may be determined in terms of distance or flying time from the DF station. In both cases the following steps are required:

1. Establish the aircraft on a heading inbound to the DF station.
2. Turn the aircraft left or right 90 degrees from the inbound heading.
3. Take new bearings each 20 seconds until a 10- or 20-degree bearing change occurs.

To compute the estimated distance, obtain the true airspeed from the pilot and use the following formula, in which Time is the number of minutes for the bearing change:

$$\text{Distance} = \frac{\text{TAS X Time (minutes)}}{\text{Degrees of change}}$$

10460

50 volts, the grid must be within less than 12 volts of this value, that is, above 50 minus 12, or 38 volts to allow conduction. The steps continue until the grid voltage exceeds 38 volts. Since the fourth step is approximately 35 volts and the fifth step is approximately 41 volts, the 38-volt level is crossed between the fourth and fifth steps.

The blocked oscillator goes through one cycle of operation at the end of which C2 is discharged. Since every fifth input pulse results in an output pulse, this circuit is a 5-to-1 frequency divider.

To cause the circuit to divide by three, four, or some other value, the bias is established at some new value. For example, a bias of 36 volts would cause the crossover with cutoff voltage to occur at the end of the third pulse, making the circuit a 3-to-1 count divider. The sizes of the steps can be varied by changing the ratio of the two capacitors. For example, if C2 is changed to 0.04 μf, it will take 20 percent of the charge, and the 38-volt level is crossed at the end of the third pulse, causing division at a 3-to-1 ratio.

In practice, frequency division can be carried to the extent that with six successive frequency dividers, a 100,000 cps sine wave can be reduced to 50 cps. The final circuit is triggered on each two-thousandth cycle of the original voltage.

AUTOMATIC FREQUENCY CONTROL (AFC)

The term AFC refers to an automatic system incorporated in a radio or radar receiver circuit for the purpose of maintaining the correct local-oscillator frequency. Almost all Navy radar equipment utilizes an AFC system.

Transmitters that produce frequencies in the UHF and microwave ranges have poor frequency stability. This is caused by factors which have negligible effect at lower frequencies. A partial listing of the cause of frequency instability at UHF and microwave ranges in transmitter oscillators and local oscillators is as follows:

1. Small physical size. Since the frequency determining components are small in physical size any condition that changes their shape or size causes a shift in frequency. Factors that cause these components to change their characteristics are vibrations, variations in temperature, and variations in atmospheric pressure.

2. Frequency pulling. This is the result of load variations which are caused by variations in the length of transmission lines, or reflections from nearby objects such as sea return, aircraft surfaces, or the radome. (This was mentioned previously in chapter 12 of this course.)

3. Frequency pushing. This is caused either by variations in the source of power or by poor regulation in the equipment's power supply.

Because of the previously presented inherent conditions it is important that the tuning of a microwave receiver to the proper frequency be automatic.

Some of the properties of microwave oscillators which may be used for frequency control are as follows:

1. Those of a magnetron-mechanical, thermal, and varying flux field density.

2. Those of a klystron-mechanical, thermal, and electrical.

The system most often used and the one described for the purpose of enabling you to gain a fuller understanding of AFC is the system which controls the repeller voltage of the local oscillator. This is the more practical method because a change in frequency is nearly linear with a change in voltage; also, changes up to 60 megacycles are practical. The operation of this type of oscillator, known as the klystron, is explained in detail in chapter 12.

CLASSIFICATION OF AFC SYSTEMS

AFC systems are classified in accordance with their method of operation. The method of operation may be divided into two major classifications, the absolute and the difference frequency systems.

In the absolute frequency system the frequency of oscillation is determined by a precision frequency standard such as a high-Q cavity. This system is generally used to keep the receiver tuned to the beacon frequency. In the difference frequency system the local oscillator is maintained on a frequency which is greater or less than the magnetron frequency by an amount equal to the intermediate frequency. This keeps the receiver tuned to the magnetron during search operation.

Either of these systems may be a nonhunting or hunting type construction. The hunting system is constructed to cause the oscillator to sweep a wide frequency range. This enables the oscillator to find the correct operating

1063 1044

To compute the estimated flying time from the DF station use the following formula:

$$\text{Time} = \frac{60 \text{ X Time (minutes)}}{\text{Degrees of change}}$$

EXAMPLE: TAS = 180; time of bearing change = 10 minutes; degrees of bearing change = 20 degrees:

SOLUTION FOR DISTANCE:

$$\text{Distance} = \frac{180 \times 10}{20}$$

Distance = 90 miles; or

SOLUTION FOR TIME:

$$\text{Time} = \frac{60 \times 10}{20}$$

Time = 30 minutes

PORTABLE TRAFFIC CONTROL LIGHT

The portable traffic light is used to control the movement of personnel and vehicles on the landing area and the landings and takeoffs of aircraft not equipped with radio. It is a directive light which emits an intense, narrow beam. Signals from the light are readily discernible to the pilot of any aircraft visible to the tower operator.

The portable traffic light (fig. 4-18) consists of a mica composition case, a reflector mounted inside at the back, a mechanism for controlling a choice of three different colored lights, and a socket for a light bulb. The light selector mechanism consists of two filters, one red and one green, mounted vertically on two arms that extend into a horizontal position from the front to the back. These arms are connected to the light selector handle underneath the case, thus enabling the operator to select the appropriate color. In addition, the selector handle aids in aiming the light. By turning this handle fully clockwise, the red filter is in place, giving a red light; fully counterclockwise puts the green filter in place.

The intermediate position, in which neither filter is in place (both at the side of the case),

AC.33

Figure 4-18.—Portable traffic control light.

produces the clear or white light. The switch that controls the light is in a pistol type grip located toward the rear of the light underneath the case. The switch is a spring-loaded toggle switch that automatically opens the circuit when released. This feature enables the operator to flash the selected color or to hold the toggle switch down when a steady color is desired. The portable traffic light is normally installed in control towers from overhead by means of a cable on pulleys and counterbalanced by weights. This keeps the light within reach for the controller's instant use and in an out-of-the-way position when not in use.

The Air Controlman should be thoroughly familiar with the limitations of the traffic control light, and evaluate its capabilities in connection with its use. The traffic control light has a range of 15 miles at night and 10 miles during daylight hours. It has the following advantages:

1. Requires no radio equipment in the aircraft; therefore, all aircraft can be controlled whether or not they possess radio.

2. Provides an emergency method of control in event of radio failure—either in the tower or the aircraft.

3. In event of power failure in the tower, the light kit includes a battery cable and connections for use with emergency battery power. It has the following disadvantages:

a. The pilot may not be looking at the control tower at the time a signal is directed toward him.

1046 2401

b. The information transmitted by a light signal is limited. One may transmit only an approval or disapproval of the pilot's anticipated actions to him since no explanatory or supplementary information can be transmitted.

CLOCKS

Two basic types of clocks may be found in the control tower: the large 12-hour wall clock, or the small direct-reading counter type clock in both the 12-hour and 24-hour version, which also has a second drum. (See fig. 4-19.) Some stations have a date-time stamp clock which is most useful for maintaining exact records of the time occurrence of events. Regardless of what type of timing device is utilized, it must be kept accurate at all times.

NAVAID MONITOR

At some shore air activities the navaid monitors are located within the control tower. In such cases the control tower facility is responsible for monitoring navigation aids. Figure 4-20 is an example of an air traffic control console for monitoring navaids. Basically the AN/GSA-35 in figure 4-20 provides facilities to perform the following functions:

AC.34

Figure 4-19.—Direct-reading clock.

AC.35

Figure 4-20.—AN/GSA-35 air traffic control console.

1. Monitor and display the status of TACAN, VOR, and UHF HOMER transmitters at remote locations.
2. Establish voice communications between the console and the remote locations.
3. Provide manual control of TACAN, VOR, and UHF HOMER transmitters, using the telephone dial.
4. Provide a visual and aural alarm should failure occur at the transmitter location.

10462

5. Voice modulate the VOR and UHF HOMER transmitters.

6. Shut down or restore to operation any, or all, of the transmitters at the transmitter locations.

The control panel on the AN/GSA-35 is divided into four modular subpanels. Three of the subpanels contain the necessary switches and lamps to control and monitor a particular navaid transmitter. The subpanel on the left of the console is a dial control panel which is used in conjunction with the other subpanels to perform the required functions.

Where an indication of navaid status is required at positions other than the location of the main console, a remote indicator illustrated in figure 4-21 may be installed to provide a slave indication from the main console. The navaid descriptions on the left side of the remote indicator are lighted continuously and the adjacent OFF is lighted when that particular navaid goes off the air.

Additional discussion of navaid monitoring is included in chapter 8 of this training manual.

RUNWAY VISUAL RANGE (RVR) INDICATOR

Runway visual range is a system of measuring the visibility along the runway. It is an instrumentally derived value that represents the horizontal distance a pilot will see down the runway from the approach end. It is based on the sighting of either high intensity runway lights or the visual contrast of other targets, whichever yields the greater visual range. RVR may be used in lieu of meteorological visibility in the approval of straight-in instrument approach procedures and takeoff minimums.

AC. 36

Figure 4-21.—Remote navaid status indicator.

Figure 4-22 is an example of an RVR instrument presently in operation in Navy control towers. As the figure illustrates, RVR is measured in hundreds of feet, which requires multiplying the value shown in the window by 100 to have an actual value for application to an instrument procedure or for relay to another position within the facility.

The equipment shown in figure 4-22, located below the RVR display panel, is remote control switching equipment for the purposes indicated on the dialing code card shown.

OPERATING MAINTENANCE

The air traffic control tower is a primary link in the air control system. Peak efficiency can only be maintained by insuring that all electric and electronic equipment is functioning at all times. Outages of power and malfunction of equipment will happen from time to time. Equipment performance checks and constant visual inspections of the tower equipments are necessary.

A good practice to follow is for each section, as it relieves the watch, to utilize some form of checkoff list. These checkoff lists should be completed as soon as possible (traffic conditions permitting) after going on watch. The list can be expanded or shortened as conditions warrant at any locality. Any malfunctions should be immediately brought to the attention of the electronics technicians normally assigned to the tower. Under no circumstances should a tower operator tamper with the adjustments, repair, or maintenance of the control tower equipment.

Another good practice to follow is to make periodic visual inspections of all the tower equipment. This can be accomplished during periods when traffic is light, and can be done in a matter of minutes. Any control tower equipment out of adjustment or otherwise inoperative creates hardships for yourself and your shipmates.

The maintenance, general appearance, and condition of the tower and equipment, including furniture and cleanliness of spaces, reflect directly upon the attitude and spirit of the personnel assigned. Generally, everyone has an area of responsibility under the watch supervisor or section leader. As with any task you are assigned, your actions and attitude toward

menial tasks are making impressions on your senior petty officers, and willingness to cooperate and do a good job will not go unnoticed. Most towers require that certain cleaning functions be completed prior to the change of watches; while details such as window washing are performed less frequently. Remember that towers are filled with valuable electrical and electronic equipment that must be kept clean and free of dust to perform at peak efficiency.

AC. 37

Figure 4-22.—Runway visual range indicator.

CHAPTER 5

METEOROLOGICAL ELEMENTS AFFECTING AVIATION

Naval aviation plays an important role in this country's first line of defense. Consequently, our naval aviators must be prepared to fly anywhere at any time. In order to successfully carry out this mission, teamwork is a must. You, as an Air Controlman, are a vital link in this team. Like the naval aviator, the Air Controlman is not expected to become an expert forecaster. That job is left to those specially trained in meteorology. However, the Air Controlman must have a basic understanding of weather in order to correctly and intelligently pass along weather information both to the pilot and the weather service personnel.

A thorough understanding of the material contained in chapters 5 and 6 will enable the Air Controlman to recognize not only minimum flying conditions but also any differences between the actual weather conditions, as observed from the tower, and those indicated by the current report. Also, the Air Controlman must become competent in reporting impending weather changes that, because of their unexpectedness, may not be immediately observed by the weather service personnel. At the same time weather elements in general may be transmitted to pilots for them to make an immediate decision in the interest of safety and/or survival.

PRESSURE

ATMOSPHERE

Atmosphere is measured by the atmospheric pressure of a column of air at any given place from the earth's surface to the top of the atmosphere. This weight is approximately 14.7 pounds per square inch at sea level. The atmosphere is acted upon by the forces of gravity; thus air is denser at lower levels than at higher levels due to the greater mass pushing down on it. Consequently, pressure is greater at sea level and diminishes with any increase of altitude. (See fig. 5-1.)

Instruments have been designed to measure this pressure. To calibrate these instruments, the International Committee of Air Navigation adopted 1013.2 millibars as a standard pressure at sea level. This pressure is considered when calibrating the instruments. Under standard conditions, 1013.2 millibars equal 29.92 inches of mercury when measured by a barometer at sea level with the temperature at 15°C(59°F).

The atmosphere is divided into concentric layers. Closest to the earth is the layer known as the troposphere; this layer is the one which concerns us most, since it is in this region that most of our weather occurs. Next are the stratosphere, mesosphere, and thermosphere. (See fig. 5-2.) These outer layers are important in theoretical meteorology, but for our purposes, a short discussion of the troposphere will suffice. The troposphere varies in thickness from the equator to the poles; its vertical extent is greatest over the equator (60,000 feet above sea level) and least over the poles (30,000 feet above sea level). This variation is due to the fact that the greater temperature in the region of the equator causes the air to be less dense and requires a greater volume, or tropospheric height, than at the poles where the cold air is very dense. The thickness of the troposphere varies with the seasons. It is at its highest in the summer and lowest in the winter. The area most affected is over the poles where there is the greatest seasonal contrast of temperature. The boundary between the troposphere and the stratosphere is referred to as the tropopause.

PRESSURE AND TEMPERATURE CHANGES

Atmospheric pressure varies from the standard atmosphere over all areas of the earth's surface. Areas in which pressure is

10465

AC.38

Figure 5-1.—The standard atmosphere.

10466

AC.39

Figure 5-2.—Vertical structure of the atmosphere.

greater than surrounding areas are called high-pressure areas, and those having less pressure than surrounding areas are called low-pressure areas. The atmospheric pressure at any given point on the earth's surface is constantly changing because of the movements of these high- and low-pressure areas.

In order for the sensitive altimeter and the altimeter setting indicator (discussed in chapter 4) to be read uniformly they are calibrated in accordance with the standard atmosphere as shown in figure 5-1. Also in this figure, note that the atmospheric pressure decreases at the rate of about 1 inch of mercury per thousand feet of altitude up to 10,000 feet and that in the standard atmosphere any given altitude corresponds to a specific atmospheric pressure. The reason for the existence of the standard atmosphere is for it to serve as a base for calibrating pressure-activated instruments. This standard atmosphere assumes certain values of temperature and pressure for various altitudes. The scale of the altimeter is calibrated to these assumed values. The indications read from the altimeter are those that would be correct if the temperature and pressure were standard for that particular altitude.

Atmospheric pressure and temperatures change almost constantly throughout the length of a flight; thus, the altimeter must be reset periodically. If this is not done, incorrect readings are given by the instrument. For example, if an aircraft flies from a high-pressure area into a low-pressure area, the altimeter reads too high. Going from a low to a high-pressure area, the altimeter reads too low. (See fig. 5-3.) Simple rules to remember—HIGH TO LOW READS TOO HIGH AND LOW TO HIGH READS TOO LOW. The same rules apply to the temperature changes. Flying from a low temperature area into a high temperature area, the altimeter reads too low, and from a higher temperature area to a lower temperature area, the altimeter reads too high. The amount of approximate error in the altimeter readings, due to a noncurrent setting, can be determined for the lower levels of the atmosphere by applying the following corrections:

PRESSURE CHANGE	ALTIMETER ERROR
1 inch of mercury	1,000 feet
1/10 inch of mercury	100 feet
1/100 inch of mercury	10 feet

AC.40

Figure 5-3.—Effect of pressure changes.

PRESSURE SYSTEMS

Pressure systems are either cyclones (low-pressure areas) or anti-cyclones (high-pressure areas). In the Northern Hemisphere, a general cycle of highs and lows moves through the Temperate Zones from west to east. (See fig. 5-4.)

Cyclones

A cyclone is a low-pressure system in which the barometric pressure decreases toward the center, and the windflow around the system is counterclockwise in the Northern Hemisphere. The terms low and cyclone are interchangeable. Any pressure system in the Northern Hemisphere with a counterclockwise (cyclonic) windflow is a cyclone.

Low-pressure systems with severe storm characteristics are called hurricanes, typhoons, tropical storms, tornadoes, or waterspouts to identify the exact nature of the storm.

AC.41

Figure 5-4.—Directional movement of the pressure systems.

Unfavorable flying conditions in the form of low clouds, restricted visibility by precipitation and fog, strong and gusty winds, and turbulence are common in low-pressure systems.

Anticyclones

An anticyclone is a high-pressure system in which the barometric pressure increases toward the center, and the windflow around the system is clockwise in the Northern Hemisphere. Any pressure system in the Northern Hemisphere with a clockwise (anticyclonic) windflow is an anticyclone.

Flying conditions are generally more favorable in high-pressure systems than in low-pressure systems because of less clouds, better daytime visibility, light or calm winds, and less concentrated turbulent areas.

Hurricanes and Tornadoes

The two most violent atmospheric disturbances found in the United States are the tornado and hurricane. Geography plays a large part in the names given to the hurricane. In the Atlantic it is called a hurricane, and in the Pacific a typhoon.

A hurricane is a low-pressure area with a whirling eddy of air having a diameter of 60 to 1,000 miles. It is accompanied by winds of speeds as high as 175 knots. Along with the

10469

winds there is an abundance of precipitation and thunderstorm activity.

A peculiarity of the hurricane is the calm center of the storm called the eye. When the eye of the storm passes over a given locality, the wind, which has been extremely violent, suddenly decreases to a much lower intensity and at times becomes a calm and precipitation stops. After the eye passes, the violent winds, precipitation, and thunderstorm activity begin anew. The winds are blowing from the opposite direction after the passage of the eye.

A tornado consists of a funnel cloud with a violently whirling center. It is usually a quarter of a mile or less in diameter. The length of a tornado's track on the ground may be from a few hundred feet to 300 miles, the average being around 25 miles. Winds in the vortex of a tornado may exceed 500 knots. The speed of the tornado over the earth's surface is comparatively slow, usually 25 to 50 knots.

Because of a tornado's highly localized nature and its erratic tendencies, it is impossible for the meteorologists to forecast the exact location at which one will strike. However, forecasting centers do broadcast notices when conditions are favorable for tornado formation in specified areas.

AIR MASSES

An air mass is defined as any huge body of air whose physical properties (temperature and humidity) are horizontally uniform. An understanding of the characteristics of an air mass is essential to any study of weather phenomena in the temperate regions. The weather in these regions is a direct result of the continuous alternation of the influences of warm and cold air masses. Warm air masses predominate in the summer and cold air masses predominate in the winter. However, both cold and warm air, alternately, may prevail almost anywhere in the temperate zone at any season. The basic characteristics of any air mass are temperature and humidity. These properties are relatively uniform throughout the extent of the air masses, and it is by measurement of these properties that the various types of air masses are determined.

The properties of an air mass depend directly upon the type of surface over which the air is lying. Thus, a knowledge of the type of surfaces over which the main bodies of air stagnate in the world circulation system is the basis of an understanding of air mass characteristics. These surfaces of origin are called source regions. They have a primary influence upon the characteristics of air masses. The path over which an air mass travels after expanding and leaving the source region and the length of time the air mass has been away from the source region (its age) also determines the characteristics of an air mass.

As an air mass expands and slowly moves out of its source region to influence other regions, it travels along a certain path. The surface over which this path takes the air after leaving the source modifies the air mass. For example, a warm, moist body of air moves out over cold, dry land and its characteristics are modified; therefore, moisture is lost and temperature is lowered.

Another factor which must not be overlooked in determining how an air mass is being changed or modified is the "age" of that body of air after leaving the source. For example, an air mass which has recently moved from the source region will not have had time to become modified significantly. However, an air body which has moved to a new region and stagnated for some time and is now old will have lost many of its original characteristics. It will have acquired many of the characteristics of the surface over which it now lies.

SOURCE REGION

The surface or region over which an air mass originates is called the source region. It is in this region that the basic characteristics of the air mass are acquired. In order to fulfill the requirements for a good source region, an area must be of uniform surface (either all land or all water), uniform temperature, and preferably, an area of high pressure where air has a tendency to stagnate.

AIR MASS CLASSES

Air masses are classified according to their source regions, as follows:

SYMBOL	SOURCE REGION	TEMPERATURE IN SOURCE REGION
A	Arctic	Coldest
P	Polar	Cold
T	Tropical	Warm
E	Equatorial	Warmest

frequency and automatically remain on this frequency. This system has the advantage that in the event of a sudden shift in magnetron or local-oscillator frequency the correct operating frequency is found automatically. In the non-hunting system the oscillator is manually tuned to the correct frequency and maintained electronically to this frequency.

Block Diagram of AFC System

In the single-mixer system (fig. 14-10), a portion of the transmitter pulse leaks through the TR box and beats with the local-oscillator signal in the mixer. The difference frequency, or the IF signal, appears at the output of the mixer. This IF signal is then amplified by one or two stages of IF amplification. At this point the signal follows two paths—it is further amplified and fed into the detector, and it is also fed into the AFC discriminator. The output of the discriminator is fed to either a d-c amplifier or some special control circuits which regulate the klystron reflector voltage. The regulation of this voltage changes the frequency of the klystron and enables it to oscillate at the correct frequency.

Most modern radar systems use a double-mixer AFC system, as shown in figure 14-11. The separate signal mixer and the AFC mixer are both connected to the same local oscillator. The AFC mixer is coupled to the transmission line through an attenuator which reduces the transmitted pulse and received signals by the same ratio. With this arrangement, strong signals from nearby radar, jammers, or sea return cannot affect the operation of the AFC loop. The double-mixer system is similar to the single-mixer system with the exception that it contains an AFC attenuator and separate IF stages.

DISCRIMINATOR CIRCUIT

The amplified output of the AFC mixer (fig. 14-10, is fed to the AFC discriminator. The output voltage of a frequency discriminator varies in amplitude and polarity with changes in the applied frequency. If the applied frequency is at the resonant or center frequency of the discriminator the output is zero. If the applied frequency is above or below the correct value, the output of the discriminator is either positive or negative, depending upon the direction of deviation. The operation of this type of discriminator is explained in detail in Basic Electronics, NavPers 10087-B.

PHANTASTRON AFC CIRCUIT

The AFC circuit (fig. 14-12 (A)) consists of the following:

1. IF amplifier which increase the amplitude of the IF signal.
2. Discriminator tube V4 which develops the pulse output signal proportional to the deviation of the IF signal from the IF center frequency.

Figure 14-10.—Block diagram of an AFC circuit in a radar receiver, single-mixer system.

Air masses are also classified according to the surface (water or land) over which they lie as follows:

SYMBOL	SURFACE	MOISTURE CONTENT
m	Maritime	High
c	Continental	Low

These symbols are combined to describe air masses as follows:

SYMBOL	SOURCE AND SURFACE	TEMPERATURE AND MOISTURE
cA	Continental arctic	Coldest, dry
cP	Continental polar	Cold, dry
mP	Maritime polar	Cold, moist
mT	Maritime tropical	Warm moist
cT	Continental tropical	Warm, dry
E	Equatorial	Warmest, moist

Air masses are further classified according to their thermodynamic characteristics; that is, according to whether it is cold or warm in comparison to the surface over which it is passing as follows:

k	Cold	Colder than the surface
w	Warm	Warmer than the surface

EXAMPLE: mPw maritime polar air warmer than the surface it is passing over.

It should be noticed that, due to the predominance of land masses or ice fields in the Arctic, mA (maritime arctic) would be a rare type. In like manner, E (equatorial air) is found exclusively over the ocean surface in the vicinity of the Equator and is designated neither c nor m but simply E.

CLOUDS

Varying weather conditions are intimately associated with different types of clouds and cloud formations. For this reason, it is highly important for the Air Controlman to be familiar with and thoroughly understand the different cloud classifications.

The international classification of clouds was established to provide a common nomenclature throughout the world for specific cummuliform and stratiform clouds. The names adopted are based upon the appearance of the clouds.

Observations have shown that clouds are generally encountered over a range of altitude varying from sea level to 25,000 feet in the polar regions, 45,000 feet in the middle latitudes, and 60,000 feet in the tropics. By convention, the part of the atmosphere in which clouds are usually present has been vertically divided into three levels—high, middle, and low. Each level is defined by a range of levels at which clouds of certain genera (classification) occur most frequently as follows:

High Clouds

1. Cirrus (Ci)
2. Cirrocumulus (Cc)
3. Cirrostratus (Cs)

The lower level of high clouds is 20,000 feet above the ground.

Middle Clouds

1. Altocumulus (Ac)
2. Altrostratus (As)
3. Nimbostratus (Ns)

The base of middle clouds may range from 6,500 feet to 20,000 feet above the ground.

Low Clouds

1. Stratocumulus (Sc)

2. Stratus (St)

The bases of the low clouds may range from near the surface to 6,500 feet above the ground.

In addition to the preceding classifications, cumulus and cumulonimbus clouds usually have bases in the lower level, but their tops often reach into the middle and high levels.

Figure 5-5 is a view of the cloud classifications being shown at their average heights.

CLOUD GENERA

Although clouds are continuously in the process of development and dissipation, they nevertheless have many distinctive features. Having

AC.42

Figure 5-5.—International classification of clouds.

10472

outlined the classifications and average level of occurrence, it is now necessary to study cloud recognition features and the weather associated with each, as well as their appearance and how they affect aviation.

Cirrus Clouds

These clouds are fibrous and delicate in appearance, looking like white wisps against the blue of the sky. They appear in a number of forms; occasionally as curls or feathery plumes. (See fig. 5-6.)

Flying conditions within cirrus clouds are good. Turbulence is negligible and the pure ice crystal composition of the cirrus clouds precludes surface icing. Cirrus clouds may indicate the first signs of approaching bad weather. Cirrus wisps, which become more and more compact and then merge into cirrostratus, may indicate an approaching warm front (fronts are discussed later in this chapter).

Cirrocumulus

These clouds appear like fleecy flakes or very small white cotton balls. The term "mackerel sky" is given to this family because the cloud pattern often appears much the same as the scales on a fish. (See fig. 5-7.) Cirrocumulus clouds are relatively rare and appear only in the presence of cirrus or cirrostratus clouds.

Cirrocumulus is a cumuliform cloud but offers only light turbulence. Due to its ice crystal composition no icing occurs on aircraft surfaces. Vapor trails can be noticed within these clouds due to the high moisture content.

Cirrostratus

Cirrostratus appears as a white veil covering all or most of the sky. It is a smooth, thin layer cloud and gives the sky a very milky appearance. It is easily recognized by the halo it produces around the sun or moon. (See fig. 5-8.)

AC.43

Figure 5-6.--Cirrus clouds.

AC.44

Figure 5-7.—Cirrocumulus clouds.

If cirrus clouds precede the cirrostratus and the cirrostratus lowers, thickens, and merges into altostratus, the approach of a warm front and bad weather is imminent.

Icing conditions and turbulence in cirrostratus clouds usually offer no hazard to flying in this cloud.

Altocumulus

Altocumulus sometimes looks like cirrocumulus, but the individual cloud balls or flakes are always larger, thicker, and grayer. The center of the underside of each cloud is dark due to the cloud's thickness. These ball-like masses often appear similar to a herd of sheep in the sky. Sometimes altocumulus is arranged in parallel bands stretching across the sky. (See fig. 5-9.)

The visibility within this cloud is poor, and the cloud usually lacks continuity. Turbulence and icing are light to moderate. The icing, if present, is usually the clear type (types of airfoil icing are discussed later in this chapter).

Altostratus

Altostratus appears as a thick gray or blue-gray smooth overcast. It is thicker and less transparent than cirrostratus, which often lowers and gradually merges with altostratus of the approaching warm front. The sun or moon shines through altostratus weakly as through ground glass. (See fig. 5-10.)

This cloud is composed of waterdrops, but ice crystals may also be present in upper levels. The icing conditions are light to moderate and predominantly form rime ice. Turbulence is light. The thickness is usually between 1,000 to 5,000 feet, but in some cases may be somewhat thicker. Visibility within the cloud averages between 50 to 200 yards. Precipitation falls from altostratus in the form of light rain or snow.

Nimbostratus

Nimbostratus is a thick, dark, gray cloud. (See fig. 5-11.) It is ominous and formless in appearance. Rain, snow, or other precipitation is actually falling from this cloud, whether it reaches the surface or not. The sun or moon

10474

AC.45

Figure 5-8.—Cirrostratus clouds.

disk is not visible through nimbostratus. There are also ragged scud clouds below the base of the nimbostratus. Turbulence and icing may be moderate to heavy with very poor visibility within and below nimbostratus.

Nimbostratus clouds are almost always in the middle cloud genera, but usually extend into the lower cloud genera. Low ragged clouds frequently occur below the nimbostratus layer, with which they may or may not merge.

Stratocumulus

Stratocumulus usually occurs as an extensive and fairly level layer marked by thick rolls and dark rounded masses of cloud. Its cloud masses are larger, thicker, and darker than those of altocumulus. They may have either small or large breaks between the rolls, however, they may form a continuous layer without any breaks. (See fig. 5-12.)

The visibility within this type cloud is poor. Turbulence in stratocumulus clouds is light to moderate, and the icing conditions are moderate and may form clear ice. The precipitation from stratocumulus clouds is generally showers of rain or snow.

Stratus

Stratus is a flat, shapeless, rather uniform layer of clouds which appear dull gray. (See fig. 5-13.)

Stratus yields precipitation in the form of drizzle only. Visibility within stratus is very poor. Only light turbulence and light to moderate icing may be present. Visibility below the base of stratus is very poor if drizzle is occurring.

Cumulus

Cumulus clouds are dense clouds with vertical development. Their upper surfaces are dome shaped and exhibit rounded protuberances, while their bases are nearly horizontal. Strong updrafts exist under and within all cumulus formations. In fact, cumulus clouds are caused

AC.46

Figure 5-9.—Altocumulus clouds.

by updrafts. Turbulence and icing conditions of varying intensities are common within cumulus clouds, depending upon the extent of vertical development.

Cumulonimbus

Cumulonimbus are cumulus clouds with great vertical development. Tops may extend higher than 60,000 feet. The top is composed of ice crystals and often resembles an anvil. (See fig. 5-14.) For more information on cumulonimbus, refer to the section titled Thunderstorms at the end of this chapter.

FRONTS AND ASSOCIATED WEATHER

A front is defined as a boundary, or line of discontinuity, separating two different air masses. From the definition, you can see the close relationship that exists between air masses and fronts. In fact, without the air masses there would be no fronts. A front is a surface, like a thin elastic sheet, separating two air masses.

In our discussion of air masses, we learned that when air stagnates over certain regions it acquires properties from the underlying surface and forms an air mass. In time, these air masses move out of their source region. Due to the general circulation of the atmosphere, terrain, and other factors, the cold air from polar regions tends to move southward while the warm air from tropical regions tends to move northward in the Northern Hemisphere. Therefore, it is inevitable that somewhere in the middle latitudes, these air masses meet. Upon meeting they do not mix readily; each air mass

10476

AC.47

Figure 5-10.—Altostratus clouds.

tending to remain intact. The surface which separates the air masses is called a frontal surface. This frontal surface, or line, is drawn on the surface weather maps, and its boundary is called a front. (See fig. 5-15.)

As previously stated, a front is indicated on a surface map by a line separating two air masses. However, this is a picture only of the surface conditions. These air masses also have vertical extent. (See fig. 5-16.) A cold air mass, being heavier, tends to underrun a warm air mass. Thus, the cold air is below and the warm air is above the surface of discontinuity. The slope of a frontal surface is usually between 1 to 50 (1 mile vertical for 50 miles horizontal) and 1 to 300 (1 mile vertical for 300 miles horizontal). For example, 100 miles from the place where the frontal surface meets the ground, the frontal surface might be somewhere between 2,000 feet and 2 miles above the earth's surface, depending on the slope. The slope of a front is of considerable importance in understanding the weather along the front.

COLD FRONTS

When cold air invades a region occupied by warm air, it wedges under the warm air pushing it upward. The frontal surface in this case is called a cold frontal surface and its intersection with the earth's surface is called a cold front. (See fig. 5-17.)

There are certain weather characteristics and conditions that are associated with the passage of cold fronts. In general, the temperature and humidity decrease, the pressure rises, and in the Northern Hemisphere the wind shifts clockwise (usually from southwest to northwest) with the passage of a cold front. The distribution and type of cloudiness and the intensity and distribution of precipitation depend primarily on the vertical velocities, stability and moisture

AC.48

Figure 5-11.—Nimbostratus clouds.

in the warm air mass. On the basis of these factors, cold fronts are classified as slow- and fast-moving cold fronts.

With the slow-moving cold front there is a general upglide of warm air along the entire frontal surface except for pronounced lifting along the lower portion of the front. The average slope of the front is approximately 1:100 (1 mile vertical to 100 miles horizontal). The cloud and precipitation area is extensive and is characterized by cumulonimbus and nimbostratus clouds, showers, and thunderstorms at, and immediately to the rear of, the surface front. This area is followed by a region of rain and nimbostratus clouds merging into a region of altostratus clouds and then cirrostratus clouds, which may extend several hundred miles behind the front. The development of cumulonimbus clouds, showers, and thunderstorms is largely dependent on the original instability characteristics of the warm air mass. Within the cold air mass there may be some stratified clouds in the rain area, but there are no clouds beyond this area unless the cold air mass is unstable. In the latter case, some cumulus clouds may develop. This type of front is usually slow moving; 15 knots may be considered average. (See fig. 5-18(A).)

With the fast-moving cold front, there is descending motion of the warm air along the frontal surface at high levels and the warm air near the surface is pushed vigorously upward. This type of front has a slope of 1:40 to 1:80 and usually moves rapidly; 25 to 30 knots may be considered as an average speed of movement. As a result of these factors, there is a relatively narrow but often violent band of weather. If the warm air mass is conditionally unstable and moist, cumulonimbus clouds, showers, and thunderstorms occur just ahead of and at the surface front, and rapid clearing occurs behind the front. Frequently altostratus and altocumulus cloud layers form and drift ahead of the main cloud bank. The more unstable the warm air mass, the more violent the weather. If the warm air is relatively dry, this type of front may not produce precipitation or clouds. It is with the fast-moving cold front that squall lines are associated. (See fig. 5-18(B).)

The Air Controlman should note that cold fronts are indicated in blue penciled lines on a colored weather map. When color cannot be used, triangles are spaced along the line of the

AC.49

Figure 5-12.—Stratocumulus clouds.

AC.50

Figure 5-13.—Stratus clouds.

front with their points indicating the approximate direction in which the cold front moves across the earth's surface.

WARM FRONTS

If cold air is retreating before an advancing mass of warm air, the warm air slides over the cold air. The frontal surface in this case is called warm frontal surface and its intersection with the earth's surface is called a warm front. (See fig. 5-19.)

The weather associated with a warm front varies as it does with a cold front, depending on the degree of stability and moisture of the warm air mass. (See fig. 5-20.)

Certain characteristics and weather conditions are associated with the passage of warm fronts. In the Northern Hemisphere the winds veer from southeast to southwest or west, but the shift is not as pronounced as with the cold front. Temperatures are colder ahead of the front and are warmer after passage of the front. Not being greatly affected by daily heating and cooling of the earth's surface, the dewpoint is normally more constant than is the temperature through the day except with the passage of a front. Therefore, the dewpoint is a good index of frontal passage. The average slope of a warm front is 1:150 (1 mile vertical to 150 miles horizontal).

A characteristic phenomenon of a typical warm front is the sequence of cloud formations. These formations are noticeable in the following order: cirrus, cirrostratus, altostratus, nimbostratus, and stratus. The cirrus clouds may appear 700 to 1,000 miles ahead of the surface front followed by cirrostratus about 600 miles and altostratus about 500 miles ahead of the surface front. Precipitation in the form of continuous or intermittent rain, snow, or drizzle is frequent as much as 300 miles in advance of the surface front. The precipitation is associated with nimbostratus above the frontal surface and stratus within the cold air. However, when the warm air is convectively unstable, showers and thunderstorms may occur in addition to the steady precipitation.

Clearing usually occurs after the passage of a warm front, but under some conditions drizzle and fog may occur within the warm sector. Normally, the speed of a warm front is less than that of cold fronts; an average may be considered to be about 10 knots.

10479

AC.51

Figure 5-14.—Cumulus and cumulonimbus clouds.

Warm fronts are indicated by red penciled lines on a colored weather map. When color cannot be used, half circles are spaced along the line of the front on the map on the proper side to indicate the approximate direction of the frontal movement across the surface.

OCCLUDED FRONTS

An occluded front occurs when a cold front overtakes a warm front. One of the two fronts is lifted aloft, and the warm air between the fronts is shut off from the earth's surface. An occluded front is often referred to as an occlusion. The type of occlusion is determined by the temperature difference between the cold air in advance of the warm front and the cold air behind the cold front.

If the air in advance of the warm front is colder than the air behind the cold front, the cold front rides along the warm frontal surface and the occluded front is referred to as a warm type occlusion. If the cold air ahead of the warm front is warmer than the cold air behind the cold front the cold frontal surface underruns the warm front and the occluded front is called a cold type occlusion. (See fig. 5-21.)

The primary difference between a warm type and cold type occlusion is the location of the associated upper front in relation to the surface

Figure 14-11. —Block diagram of a double-mixer AFC system.

3. Pulse amplifier V3.
4. AFC sweep generator V2 with its diode control tube V1.

Discriminator

The discriminator consists of a twin-diode rectifier, which determines the intermediate frequency that will be maintained by the AFC system. If an intermediate frequency is applied to the AFC search input and it is increased in frequency from approximately 25 to 35 mc, the rectified discriminator output will vary correspondingly from a positive d-c voltage to zero at 30 mc to a negative d-c voltage after the crossover is passed. (See fig. 14-12 (B).)

This variation in intermediate frequency is caused by changing the frequency of the klystron from low to high by varying its repeller voltage. The AFC circuit does this automatically when not locked in. Thus, the discriminator output falls from a positive value on the low side of the center frequency to zero at 30 mc. This output variation does not influence the AFC sweep generator. On the high side the discriminator output is negative, the proper polarity for controlling the sweep.

The discriminator circuit is similar to that of a conventional discriminator; however, instead of using mutual coupling, output from the last AFC IF amplifier is capacitively coupled to the discriminator input circuit.

Pulse Amplifier

Output pulses from the discriminator diode circuit are coupled to the pulse amplifier, V3 which amplifies and inverts the pulses that enable the sweep control tube to lock in the AFC sweep.

AFC Sweep Generator

The AFC sweep circuit consists of sweep generator V2 which, when free-running, generates a slow sweep to vary the klystron frequency over a wide range, and control tube V1, that locks the sweep on positive pulses. When the klystron frequency being swept reaches a point where it beats with the RF pulses from the magnetron and causes the intermediate frequency to increase past the 30 mc center frequency, positive output pulses from the discriminator amplifier lock in the AFC sweep generator at the pulse repetition frequency, and limit the klystron frequency sweep to a low amplitude, producing only a small variation about the correct intermediate frequency. Negative pulses from the pulse amplifier tube do not affect the free-running sweep. Actual locking-in of the sweep generator is performed by a diode control tube, V1.

Free-Running Sweep

To understand the operation of the AFC sweep tube when free-running, assume that the cycle is where the plate voltage begins to fall. (See fig. 14-12 (C).) When this occurs, the suppressor has a high positive potential because of the coupling, through C3, of a positive voltage developed by the previous sharp rise in screen voltage. This positive suppressor potential initiates the plate-current increase that produces the decline in plate voltage. The decline of plate voltage is modified as the negative charge at the plate is applied through capacitor C3.

During this decline, the applied control grid voltage gradually becomes less negative. As

front. In a warm type occlusion the upper cold front precedes the surface occluded front by as much as 200 miles. In the cold type occlusion the upper warm front follows the surface occluded front by 20 to 50 miles.

Since the occluded front is a combination of fronts, the resulting weather is that of the cold front's narrow band of violent weather and the warm front's widespread area of cloudiness and precipitation occurring in combination along the occluded front. The most violent weather occurs at the tip of occlusion. (The tip is the point at which the cold front is overtaking the warm front.)

Occluded fronts are indicated by a purple penciled line on the colored weather map. When color cannot be used, alternating half circles and triangles are spaced along the line of the front on the map and on the proper side to indicate the approximate direction of frontal movement across the surface.

STATIONARY FRONTS

One of the most annoying characteristics of a stationary front (a front that shows little or no apparent movement) is that it may greatly hamper and delay air operations by persisting in an area for several days.

The weather associated with a stationary front varies with the stability of the warm air or the moisture content of the cold air. (See fig. 5-22.)

If the warm air is unstable, rainfall from thunderstorms normally exists. If the warm air is stable, there generally is drizzle, and beyond the freezing level there are icing conditions, light snow, or light rain. At very high levels there are also some ice type clouds present.

In the cold air there are generally lowered ceilings and extensive fog. Icing conditions, if present, are light.

The width of the weather band with its precipitation and low ceilings varies from 50 to 200 miles, depending upon the temperature of the air mass.

Stationary fronts are indicated by an alternating red and blue penciled line on the colored weather map. When color cannot be used, alternating half circles and triangles are spaced along the line of the front on opposite sides of the frontal line to indicate very little movement across the surface.

HUMIDITY

Weather conditions depend greatly upon the amount of water in the air. The water may be

AC.55

Figure 5-18.—Vertical cross section of a cold front. (A) Slow-moving cold front; (B) fast-moving cold front.

10483

SPAOI

Figure 5-19.—A warm front.

in any of three forms—gas, liquid, or solid. As a gas, it is called water vapor, which is invisible. Solid or liquid water is visible as precipitation or as clouds.

Humidity is a comprehensive concept; therefore, there are available many different definitions and many different manners of expressing humidity.

Most of the weather that interferes with the operation of aircraft is directly associated with water in some form. In this section, the characteristics of water vapor and two manners in which humidity is expressed are discussed.

WATER VAPOR CHARACTERISTICS

Water vapor is a universal constituent of the atmosphere. Any given volume of atmosphere at a given temperature can contain only a certain maximum quantity of water vapor. The maximum amount (by volume) of water vapor that the air can hold is about 4 percent. If more and more water vapor is injected into a given container of dry air kept at a constant temperature, a point is reached when the water vapor condenses, or becomes liquid, as fog within the container or as dew on its walls. As more and more water vapor is added, more of it condenses; but the total amount of vapor in the container remains unchanged, although the amount of liquid water in the form of fog or dew increases. The volume of air in the container is then said to be saturated with water vapor.

Although the quantity of water vapor in a saturated volume of atmosphere is independent of the amount of air present, IT DOES DEPEND ON THE TEMPERATURE. The higher the temperature, the greater the tendency for liquid water to turn into vapor. At a higher temperature, therefore, more vapor must be injected into a given volume before the saturated state is reached and dew or fog forms. On the other hand, cooling a saturated volume of air forces some of the vapor to condense and the quantity of vapor in the volume to diminish.

DEFINITIONS OF HUMIDITY

The actual amount of water vapor contained in the air is usually less than the saturation amount. The amount of water vapor in the air is expressed in several different manners. Two methods are described in the following portion of this section.

10484

AC.57

Figure 5-20.—Vertical cross section of a warm front.

Relative Humidity

Although the major portion of the atmosphere is not saturated, it is desirable to be able to say how near it is to being saturated. This relationship is expressed as relative humidity. The relative humidity of a volume of air is the ratio (in percent) between the water vapor actually present and the water vapor necessary for saturation at a given temperature.

Assume, for instance, that the temperature is 25° C. The amount of water vapor needed to saturate a cubic meter of air at this temperature is 23.05 grams. If observation indicates only 11.525 grams of vapor in a cubic meter,

AC. 58

Figure 5-21.—Vertical cross section of cold and warm type occlusions.

the sample volume is half saturated, or its relative humidity is 50 percent.

Relative humidity shows the degree of saturation, but it gives no clue as to the actual amount of water vapor in the air. Thus, other expressions of humidity are useful.

Dewpoint

The dewpoint is the temperature to which air must be cooled, at constant pressure and constant water vapor content, in order for saturation to occur. The dewpoint is a conservative and very useful element. When atmospheric pressure stays constant, the dewpoint reflects increases and decreases in moisture in the air, and also shows at a glance, under the same conditions, how much cooling of the air might result in condensed moisture.

FOG

Since the Air Controlman's job is primarily one of helping pilots by relaying known and anticipated information to them, it is essential that he have a fundamental knowledge of the classes and causes of fog.

Fog may be defined as a cloud on the earth's surface. It is a visible condensation in the atmosphere of sufficient density to interfere with visibility.

Fog consists of visible water droplets or ice particles suspended in the atmosphere. It differs from other clouds in that it exists on the ground or over the surfaces of bodies of water. It differs from rain or mist in that its water or ice particles are more minute, are suspended, and do not fall earthward.

FORMATION OF FOG

The differential between the dewpoint and the temperature is used in the prediction of fog formation. The smaller the difference between the temperature and dewpoint, the greater the possibilities of fog formation. Spread is the term used to define the difference in degrees between the two. All Air Controlmen should be alert to the possibility of fog formation whenever the spread decreases to 4 degrees or less.

There are two ways in which the temperature and dewpoint may become coincident:

1. The dewpoint rises until it equals the temperature. This results from the addition of water vapor to the air by evaporation from water surfaces, wet ground, or precipitation falling through the air.

2. The temperature lowers to the dewpoint as a result of cooling of the air by contact with a cold surface underneath.

Naturally, other factors influence the formation of fog. Wind is one. In a calm condition, fog will form and is generally very shallow. However, a light wind condition is ideal for fog formation, as it produces deep layers of fog. A moderately strong wind tends to keep fog from forming as it circulates the air too rapidly for fog producing conditions to exist. Strong wind will often dissipate fogs already formed.

Air polluted with dust and smoke particles provides a great quantity of condensation nuclei.

10486

AC. 59

Figure 5-22.—Cross section of a stationary front.

These nuclei, offering particles of matter upon which moisture may condense, make fog formation much easier and the fog more dense. Although all fog can reduce the ceiling and visibility to near zero, the most dangerous type of fog is one that covers large areas.

CLASSES

Fog is divided into two classes: air mass fog and frontal fog. Each class is discussed as there are different requirements which govern the formation of each class.

Air mass fog occurs within a given air mass and is formed when the layer of air close to the earth's surface is cooled by contact with a colder surface below.

There are four types of air mass fog. Each type gets its name from the particular manner in which air is cooled to the dewpoint or saturated to condensation. The four types are radiation fog, advection fog, upslope fog, and steam fog.

Radiation fog, which generally occurs as ground fog, is formed by the cooling of a land surface on clear nights by radiation of heat to the sky. (See fig. 5-23.) Radiation fog never forms over water.

After sunset, the earth receives no heat from the sun, but continues to radiate heat. The surface begins to cool because of this heat loss. As the earth cools, the layer of air next to the earth's surface is cooled by conduction. If the layer of air next to the surface is sufficiently moist, the conduction process chills the air to the dewpoint temperature and fog forms. In case of a calm wind, this cooling by conduction affects only a very shallow layer of air. In this case, the fog tends to be very thin. Wind from three to five knots provides enough mixing so that the fog will be fairly deep. If the wind is too strong, it causes so much mixing that fog does not form. Radiation fog usually forms at night and generally dissipates before midmorning. The best condition for radiation fog is a clear cool night, light wind, and high humidity.

Advection fog is the name given to fog produced by air in motion or fog formed in one place and transported to another. This type of fog is formed when air is transported over a land or water surface colder than the air mass passing over it. (See fig. 5-24.) Cooling from below takes place and gradually builds up a layer of fog.

Advection fog forms in regions where marked temperature contrasts exist within a short distance of each other, and only when the wind blows toward the cold region. Areas of marked temperature contrast are usually found along

AC.60

Figure 5-23.—Radiation fog.

the coastlines, places where snow covered ground is adjacent to bare ground, and at sea where cold and warm water currents are adjacent.

Due to the fact that advection fog covers larger areas than the other types, it is generally considered the most dangerous type.

Upslope fog forms when air is forced to ascend a gradual slope. As the air rises up the slope, the atmospheric pressure decreases causing the air to expand and cool. If the air cools to a temperature equal to the dewpoint temperature, fog will form. Upslope fog forms in very deep layers and requires considerable time to dissipate. The most common fog of this type is called Cheyenne fog and is caused by the westward flow of air from the Missouri valley, which produces fog on the eastern slope of the Rocky Mountains. (See fig. 5-25.)

Steam fog, sometimes referred to as sea smoke, occurs within air masses. However, unlike other air mass fogs which are formed by cooling of the air temperature to the dewpoint temperature, this type is caused by saturation of the air through evaporation of water. It occurs when cold air moves over warm water. Evaporation from the surface of the warm water easily saturates the cold air, causing the fog to form. This type of fog is most common in the northern latitudes. Marsh or swamp mist is a familiar example of steam fog. This type of fog generally forms in the fall of the year only. (See fig. 5-26.)

10488

AC.61

Figure 5-24.—Advection fog.

Frontal fog is another hazard which must be added to the list of weather troubles associated with fronts. Frontal fog forms under the frontal surface in the cold air mass. Frontal fog is divided into two classes: warm front fog and cold front fog.

The warm front fog is much more extensive than the cold front type and is a definite hazard to flight operations. It is caused by rain falling from warm air into the cold air beneath the front, and is anticipated by a rise in the dewpoint to or very near to the free air temperature. (See fig. 5-27.)

Since the precipitation band accompanying a warm front is quite wide and the movement of the front is slow, this warm front fog may cover an extensive area for considerable time. After the passage of a warm front, an advection type fog frequently occurs in the warm air if the surface is much colder than the air that is moving in. Strictly speaking, this is not a frontal type fog, but is formed within the air mass itself by advection cooling.

Warm front fog is particularly prevalent along the eastern seaboard of the United States, where the cold waters offshore and the general unslope of the terrain are contributing factors toward this fog formation.

Cold front fog is comparatively rare because cold fronts move so rapidly and have associated with them such narrow bands of precipitation

AC.62

Figure 5-25.—Upslope fog.

and high wind speeds that fog conditions dissipate or do not develop. On some infrequent occasions, fog does form in the cold air mass just behind the cold front (See fig. 5-27.) When this happens, the fog dissipates rapidly due to the fast movement of the front over the surface of the earth.

AIRFOIL ICING

Another weather hazard to flying is airfoil icing. The Air Controlman who has exact knowledge of when and how ice forms on aircraft is able to lend invaluable assistance to pilots at one time or another.

Formation of ice on an aircraft reduces lift and thrust by adding weight to the structure and changing the airfoil shape of wings, tail, and propeller(s). There are three types of airfoil ice: rime, clear (glaze), and frost. Icing conditions encountered in flight will be a combination of rime and clear ice types with the characteristics of one or the other being dominant. Frost forms on aircraft while on the ground. An everyday comparison between rime ice and clear ice may be found in a home refrigerator. The ice that forms in the ice tray is an example of clear ice. It is very hard and glassy, and can be broken loose only with difficulty. Rime ice is the ice that forms on the refrigerator's coils. It is white and granular, and can be easily broken off. There are only two fundamental conditions necessary for the formation of ice on aircraft in flight. The aircraft must be flying through visible water in the form of rain, drizzle, or cloud droplets; and at the time the water droplets strike the aircraft, their temperature, or the temperature of the surface of the aircraft, must be 32°F or colder. The heaviest airfoil icing will generally occur within the temperature range of 0° C to -10°C (32° F to 15° F) provided moisture is available.

CLEAR ICE

Clear ice, sometimes referred to as glaze ice, is considered to be the most serious of the

Figure 14-12.—(A) Phantastron AFC circuit; (B) AFC lock-in frequency waveform; (C) AFC sweep generator waveforms.

1046

Figure 5-26.—Steam fog.

AC.63

Figure 5-27.—Warm and cold front fog.

AC.64

ID491

three types. It is clear, dense, and solid, adhering firmly to structures upon which it forms. (See fig. 5-28.) If the water droplets strike an aircraft in such rapid succession that none has a chance to freeze before the next strikes in the same place, the leading edges of the aircraft structures are kept covered by a film of liquid water. This film of water, cooled by contact with the colder air and by partial evaporation, freezes from the inside out forming a clear, dense, strong layer of ice attached to the wing or other surfaces upon which it is freezing.

Some of the conditions which produce a liquid film of water on aircraft favorable to the formation of clear ice are as follows:

1. Large water droplets such as found in cumuliform clouds.
2. Large number of cloud droplets (dense clouds).

These first two conditions are most commonly found in unstable air.

3. Temperature just slightly below freezing.
4. An unstable or conditionally unstable air mass.
5. Rain or freezing rain.

RIME ICE

Rime ice is a granular, whitish, opaque, rough deposit of ice formed from tiny supercooled water drops found in stratiform clouds of stable air. (See fig. 5-29.) Rime ice usually occurs at a lower temperature than does clear ice.

Unlike clear ice, rime is formed as each supercooled water droplet that strikes the airfoil freezes completely before another strikes in the same place. The resulting ice deposit is in the form of tiny pellets frozen together in a spongy mass.

Figure 5-28.—Clear ice on an airfoil.

AC.65

AC.66

Figure 5-29.—Rime ice on an airfoil.

The conditions which favor formation of rime ice are as follows:

1. Very small droplets such as found in stratiform clouds.
2. A relatively small number of water droplets found in clouds that are not dense.
3. Temperatures far below freezing.
4. An air mass that is stable or conditionally stable.
5. Drizzle.

FROST

Frost is a light, whitish, feathery crystalline structure, snowlike in character. It forms a dangerous coating on an aircraft surface which adds drag and alters the aerodynamic characteristics of an aircraft. Frost occurs when the temperatures of the surfaces of the aircraft are below freezing at the time condensation takes place. This icing condition usually forms on aircraft on the ground. It can also form on airborne aircraft if the aircraft very quickly flies from a region where the temperature is well below freezing to a region where the temperature is considerably higher and the air is very moist.

Other parts of the aircraft susceptible to icing which will decrease its flight capabilities are the propeller, pitot tube, and carburetor. Propeller ice reduces the power of the aircraft; pitot tube ice causes malfunction of the air speed indicator; and carburetor ice gives the effect of slowly closing the throttle. It occurs under a wide range of temperatures and can result in complete engine failure. Carburetor ice forms during vaporization of fuel combined with the expansion of air as it passes through the carburetor. Temperature drop in the carburetor can be as much as 40° C, but is usually 20° C or less. The temperature at which carburetor

10493

10493

icing will form depends upon many factors such as relative humidity, type of gas and its ingredients, and the type of carburetors.

WINDS

In general, a reference to wind means air in natural horizontal motion relative to the surface of the earth. Actually, wind has many components of direction. It may be directed vertically upward or downward, or horizontally. The vertical components are difficult to measure. Thus we deal only with the horizontal components—the horizontal direction and speed. In meteorology, reference is generally made to the vertical component of the wind as turbulence, updrafts, or downdrafts.

The cause of windflow is the variation in pressure, which in turn results from a variation in temperature caused by the global circulation of air which maintains a balance of heat on the earth. Since the earth heats unequally, the heat is carried away from a hotter area to a cooler one as a result of the operation of physical laws.

At times confusion arises from the meaning of wind direction. Wind direction is always the direction FROM which the wind is blowing. Windspeed is usually measured and expressed in knots.

PHOTOMETEORS

Photometeors are luminous phenomenon produced by the reflection, refraction, diffraction or interference of light from the sun or moon. They constitute such phenomena as solar and lunar halos, solar and lunar coronas, rainbows, fogbows. Photometeors are not active elements; that is, they generally do not cause adverse weather. However, they are related to clouds which are indicative of what weather to expect.

HALOS

A halo is a luminous ring around the sun or moon. When it appears around the sun, it is a solar halo; when it forms around the moon, it is a lunar halo. It usually appears whitish, but it may show the spectral colors. Halos are formed by REFRACTION of light as it passes through ice crystals. This means that halos are almost exclusively associated with cirriform clouds. Refraction of light means that the light passes through prisms; that is, ice crystals which act as prisms.

CORONAS

A corona is a luminous ring surrounding the sun (solar) or moon (lunar) and is formed by DIFFRACTION of light by water froplets. It may vary greatly in size, but is usually smaller than a halo. All the spectral colors may be visible. Sometimes the spectral colors or portions of them are repeated several times and are somewhat irregularly distributed. It is difficult to distinguish between coronas and halos. The main feature may be size, as previously mentioned, and the colors appear brighter, which is a result of light diffraction by water droplets. This would be associated with cumulus clouds or middle clouds.

RAINBOWS

The rainbow is a circular arc seen opposite the sun, usually exhibiting all the primary colors, with red on the outside. It is caused by diffraction, refraction, and reflection of light within raindrops.

FOGBOWS

A fogbow is a whitish semicircular arc seen opposite the sun in fog. Its outer margin has a reddish tinge; its inner margin has a bluish tinge. The middle of the band is white. An additional bow, with the colors reversed, sometimes appears inside the first.

ELECTROMETEORS

Electrometeors are visable or audible manifestation of the atmospheric electricity. The more important electrometeors include thunderstorms (because of its affect on aviation is discussed as a separate entity later in this chapter), lightning and aurora.

LIGHTNING

Lightning is a flash of light from a sudden electrical discharge which takes place from or inside a cloud or from high structures on the ground or from mountains. Four main types of lightning can be distinguished as follows:

1. Cloud to ground lightning (CG). Lightning occurring between cloud and the ground.

2. Cloud discharge (IC). Lightning which takes place within the thunder cloud.

3. Cloud to cloud discharge (CC). Streaks of lightning reaching from one cloud to another.

4. Air discharge (CA). Streaks of lightning which pass from a cloud to the air but do not strike the ground.

AURORA

Aurora is a luminous phenomena which appears in the high atmosphere, in the form of arcs, bands, draperies, or curtains. This phenomena is usually white but may have colors. The lower edges of the arcs or curtains are usually well defined while the upper edges are not. Polar aurorae are due to electrically changed particles, ejected from the sun, acting on the rarified gases of the higher atmosphere. The particles are channeled by the earth's magnetic field, so that aurorae are mainly observed near the magnetic poles.

LITHOMETEORS

Lithometeors comprise a class of atmospheric phenomena, among which dry haze and smoke are the most common examples. In contrast to a hydrometeor, which consists largely of water, a lithometeor is composed of solid dust or sand particles, or the ashy products of combusion.

HAZE

Haze is suspended dust or salt particles so small that they cannot be individually felt or seen by the unaided eye. They reduce visibility and lend a characteristic opalescent appearance to the air. Haze resembles a uniform veil over the landscape that subdues its colors. This veil has a bluish tinge when viewed against a dark background and a dirty yellow or orange tinge when viewed against a bright background.

SMOKE

Smoke is fine ash particles suspended in the atmosphere. When smoke is present, the disk of the sun at sunrise and sunset appears very red and during the daytime has a reddish tinge. Smoke at a distance, such as from forest fires, usually has a light grayish or bluish color and is evenly distributed in the upper air.

DUST

Dust is finely divided solid matter, uniformly distributed in the air. It imparts a tannish or grayish hue to distant objects. The sun's disk is pale and colorless or has a yellow tinge at all periods of the day.

SAND

Fine particles of sand picked up from the surface by the wind and blown about in clouds or sheets constitute a troublesome lithometeor in some regions.

HYDROMETEORS

Hydrometeors are composed primarily of water in either liquid or solid state. Hydrometeors comprise all forms of precipitation, such as rain, drizzle, snow, and hail, and such elements as clouds and fogs.

PRECIPITATION

Precipitation includes all forms of moisture that fall to the earth's surface, such as rain, snow, hail, drizzle, etc. Dew and frost are not forms of precipitation, although they are hydrometeors. Precipitation is classified according to both its form (liquid, freezing, and solid), size, and rate of fall.

Rain

Precipitation which reaches the earth's surface as large water droplets is classified as rain. If the droplets freeze on contact with the ground or other objects, the precipitation is classified as freezing rain.

Drizzle

Drizzle consists of very small and uniformly dispersed droplets that may appear to float while following air currents. Sometimes drizzle is referred to as mist. Unlike fog droplets, drizzle falls to the ground. However, the rate of fall is very slow. The slow rate of fall and the small size of the droplets distinguish drizzle from rain. When the droplets freeze on contact with the ground or other objects, they are called freezing drizzle. Drizzle always restricts visibility.

10495

Snow

Snow consists of white or translucent ice crystals. In their pure form the ice crystals are highly complex, hexagonally branched forms. However, most snow falls as parts of ice crystals, as individual crystals, or more commonly as clusters and combinations of these. Snow occurs in meteorological conditions similar to those in which rain occurs, except that with snow the initial temperatures must be at or below freezing.

Snow Pellets (Soft Hail)

Sometimes called soft hail, snow pellets are white, opaque, round (or occasionally conical) kernels of snowlike consistency, 1/16 to 1/4 inch in diameter. They are crisp and easily compressible. They may rebound or burst when striking hard surfaces. They occur almost exclusively in showers.

Snow Grains

Sometimes called granular snow, snow grains take the form of minute, branched, starlike snowflakes, or of very fine simple crystals. They are the solid equivalent of drizzle with diameters generally less than 0.04 inch (1 mm).

Ice Pellets

Ice pellets are composed of frozen raindrops or drizzle or largely melted and refrozen snowflakes that rebound when striking hard surfaces. Their fall may be continuous, intermittent, or showery.

Hail

Ice balls or stones, ranging in diameter from that of a medium-size raindrop to an inch or more, are referred to as hail. They may fall detached or frozen together into irregular, lumpy masses. They are composed either of clear ice or of alternating clear and opaque snowflake layers. Hail forms in cumulonimbus clouds and is associated with thundershower activity. Surface temperatures are usually above freezing when hail occurs. Determination of size is based on the diameter, in inches, of normally shaped hailstones.

THUNDERSTORMS

Intensive research is underway by various government agencies for the purpose of providing the air traffic control system with the capability to locate, identify, and measure the intensity of turbulence associated with severe weather which accompanies thunderstorms. Radar is a valuable tool in this research and much has been discovered. Although this capability does not yet completely exist, controllers must still advise pilots of known weather conditions that should be avoided.

No firm rules can be given such as to avoid thunderstorm cells by a certain number of miles. Controllers must exercise good judgment based on knowledge of thunderstorm characteristics to adequately advise and assist pilots in the accomplishment of safe flight.

FORMATION

The thunderstorm represents a violent and spectacular atmospheric phenomenon. The thunderstorm is usually accompanied by lightning, thunder, heavy rain, gusty surface wind, and frequently by hail. A certain combination of atmospheric conditions is necessary for the formation of a thunderstorm. These factors are conditionally unstable air of relatively high humidity and some type of lifting action. Before the air actually becomes unstable, it must be lifted to a point where it is warmer than the surrounding air. When this condition is brought about, the relatively warmer air continues to rise freely until, at some point aloft, its temperature has cooled to the temperature of the surrounding air. In order to bring the warm surface air to a point where it will continue to rise freely, some type of external lifting action must be introduced. Many conditions satisfy this requirement. For example, an air mass may be lifted by heating, terrain, and fronts or convergence.

STRUCTURE

The fundamental structural element of the thunderstorm is the unit of convective circulation known as a convective cell. A mature thunderstorm contains several of these cells, which vary in diameter from 1 to 6 miles. By radar analysis and measurement of drafts, it has been determined that, generally, each cell is independent of surrounding cells of the same

storm. Each cell progresses through a cycle which lasts from 1 to 3 hours. In the initial stage (cumulus development), the cloud consists of a single cell; but as the development progresses, new cells form and older cells dissipate.

The life cycle of the thunderstorm cell consists of three distinct stages; they are the cumulus stage, the mature stage, and the dissipating or anvil stage. (See fig. 5-30.)

Cumulus Stage

Although most cumulus clouds do not become thunderstorms, the initial stage of a thunderstorm is always a cumulus cloud. The chief distinguishing feature of this cumulus or building stage is an updraft, which prevails throughout the entire cell. Such updrafts vary from a few feet per second to as much as 100 feet per second in mature cells.

Mature Stage

The beginning of surface rain, with adjacent updrafts and downdrafts, initiates the mature stage. By this time the apex of the average cell has attained a height of 25,000 feet or more. As the raindrops begin to fall, the frictional drag between the raindrops and the surrounding

AC.67

Figure 5-30.—Life cycle of a thunderstorm cell.

air causes the air to begin a downward motion. The descending saturated air soon reaches a level where it is colder than its environment; consequently, its rate of downward motion is accelerated. This is a downdraft.

Dissipating (Anvil) Stage

Throughout the life span of the mature cell, more and more air aloft is being dragged down by the falling raindrops. Consequently, the downdraft spreads out to take the place of the dissipating updraft. As this process progresses, the entire lower portion of the cell becomes an area of downdraft. Since this is an unbalanced situation, and since the descending motion in the downdraft effects a drying process, the entire structure begins to dissipate. The high winds aloft have now carried the upper section of the cloud into the anvil form, indicating that gradual dissipation is overtaking the storm cell.

THUNDERSTORM WEATHER

Rain

Liquid water in a storm may be ascending if encountered in a strong updraft; it may be suspended, seemingly without motion, yet in extremely heavy concentration; or it may be falling to the ground. Rain, as normally measured by surface instruments, is associated with the downdraft. This does not preclude the possibility of a pilot entering a cloud and being swamped, so to speak, even though rain has not been observed from surface positions. Rain is found in almost every case of penetration below the freezing level. In instances in which no rain is encountered, the storm probably has not developed into the mature stage.

Hail

Hail is a possibility in any thunderstorm, and the presence of damaging hail should always be considered with moderate or severe storms.

Turbulence

Data obtained by research indicates that the frequency and severity of turbulence encounters decrease slowly with distance from the storm cores. Moderate to severe turbulence may be encountered up to 20 miles from the center of severe storms at any altitude and up to 10 miles from the centers of less severe storms. Severe turbulence is often found in the anvil cloud 15 to 20 miles downwind from the severe storm cores. The storm cloud is only the visible portion of a turbulent system whose updrafts and downdrafts often extend outside of the storm proper. Very little evidence exists that maximum turbulence occurs at the middle heights of a storm. The same turbulence considerations which apply to flight at high altitudes near storms apply to low altitudes as well. No useful correlation exists between the external visual appearance of thunderstorms and the turbulence and hail within them.

Surface Wind

A significant hazard associated with thunderstorm activity is the rapid change in surface wind direction and speed immediately prior to storm passage. The strong winds at the surface accompanying thunderstorm passage are the result of the horizontal spreading out of downdraft currents from within the storm as they approach the surface of the earth.

CHAPTER 6

AVIATION WEATHER REPORTS AND ADVISORIES

AVIATION WEATHER SERVICE

The U. S. Weather Bureau is the agency responsible for the nation's aviation weather service. It is the primary organization for providing weather service to pilots. To prepare, collect, and transmit the thousands of observations and forecasts now available to pilots would require an organization many times the size of the Weather Bureau. Therefore, the Weather Bureau obtains the cooperation of other government agencies, and private individuals and organizations to satisfy the overwhelming aviation weather service requirements.

The FAA is considered the principal distribution agency for weather information to aviation interests through its vast communications systems and pilot weather briefing service.

The military weather service cooperate extensively with the Weather Bureau at all levels by exchange of weather information. However, the military weather services concentrate their efforts toward satisfying military requirements and directly serve military interests.

TYPES OF WEATHER OBSERVATIONS

The term "observation" is used to cover both measured and estimated existing values of weather elements. Observations are made at the ground (surface), from the ground, and aloft.

Surface Observations

Surface observations are the most readily obtained. They are made by Weather Bureau personnel, military weather services personnel, and FAA Flight Service Specialists. Surface observations from Navy and commercial ships at sea further add to the weather picture. Automatic observing stations (AMOS), which automatically record wind, ceiling and precipitation information, etc., are being added to the network of surface observation sites.

Radar Observations

Radar observations afford a continuous presentation of significant cloud and precipitation patterns. These are made by Weather Bureau and military personnel at many locations.

Rawinsonde Observations

These observations are obtained by sending a balloon aloft with miniature weather observing equipment and radio gear. They furnish information on temperature, humidity, pressure and wind often to heights above 100,000 feet.

Pilot Balloon Observations (PIBALS)

PIBALS supplement the rawinsonde observations. It is a balloon sent aloft and tracked visually to determine wind information.

Pilot Reports (PIREP's)

These observations come directly from the pilot and are often relayed through the Air Controlman to the weather service personnel. Much of the time, PIREP's are the only sources of information relating to conditions such as turbulence, icing, and cloud tops.

Aerial Weather Reconnaissance Flights

The Air Force and Navy make scheduled flights along fixed routes over relatively inaccessible land and water areas with trained weather personnel aboard to make weather observations.

10499

Satellite Observations

Satellites orbiting the earth at altitudes above 400 miles furnish photographs of cloud patterns over a large area.

ANALYSES AND FORECASTING CENTERS

Some of the analyses and forecast centers of the Weather Bureau directly support aviation, while others provide general or special services. The following centers are those which directly support the aviation weather service.

National Meteorological Center (NMC)

This center is the hub of the nation's weather information processing function. It receives weather information from all over the Northern Hemisphere and provides analyses and forecasts to other weather facilities for periods of up to 30 days in the future. Other facilities may interpret NMC products without having to perform identical tasks in preparing detailed forecasts for their areas.

Flight Advisory Weather Service (FAWS) Center

FAWS centers have areas of forecast responsibility which roughly correspond with areas of responsibility of the FAA Air Route Traffic Control Centers (ARTCC's). These centers prepare and distribute aviation terminal and area forecast with the assistance of guidance material from the National Meteorological Center.

Weather Bureau Airport Stations (WBAS)

The WBAS is the Weather Bureau's main link between the aviation interest and the processing centers such as NMC and FAWS. The weatherman in a WBAS is an observer-briefer. He depends mostly on material received from the larger centers, but must do some analyses and forecasting also. The WBAS is responsible for the information given to pilots and other aviation interests.

Special Processing Centers

NATIONAL SEVERE STORM FORECAST CENTER (NSSFC).—This facility, located in Kansas City, Mo., issues warnings of severe thunderstorms and their accompanying hazards including tornadoes, funnel clouds aloft, hail at the surface, areas of extreme turbulence, and surface wind gusts of more than 50 knots.

THE NATIONAL HURRICANE CENTER.—This facility is located in Miami, Fla. All efforts concerning tropical storms or hurricanes which may affect the southern and eastern United States (U. S.) are supervised and coordinated at this center. The Weather Bureau office in San Francisco serves as the hurricane center for tropical storms of all intensities in the Pacific Ocean along the west coast of the U.S. A corresponding service for tropical storms and typhoons in the central and western Pacific is provided through joint efforts of the Weather Bureau and military weather services.

HIGH ALTITUDE FORECAST CENTERS.—These centers provide forecast of temperature, wind, and significant en route weather for high altitude operations.

THE NATIONAL WEATHER SATELLITE CENTER (NWSC).—NWSC prepares cloud analyses for distribution. The analyses are based on pictures of cloud coverage of large areas taken by the cameras of the weather satellites orbiting the earth.

WEATHER COMMUNICATIONS SYSTEMS

Weather information is extremely perishable because of its changeable nature. The distributing function is a very large one, including the collection and dissemination of observed data and the delivery of products of the analyses and forecasting centers. Existing methods for collection and distribution of weather information over long distances are teletype circuits and facsimile networks. Weather information may be transmitted by landline, which is a fixed wire circuit from station to station or from a control station to a group of stations, or by radio, which is used to transmit and receive information where the use of landline is impracticable or impossible. Radio is the means by which weather information is transmitted to ships and overseas land stations.

Teletype Circuits

The teletype circuits used for distribution of aviation weather information are service A, C, and O, operated by the FAA, and military teletype networks.

10500

the plate voltage reaches minimum, the negative voltage applied to C2 ceases, and the control grid potential rises positively. Because of the low potential of both the suppressor and plate at this time, the grid-voltage change causes a rapid increase in screen current; the resulting negative voltage, coupled from the screen through capacitor C3 to the suppressor, drives this element sharply negative, cutting off the plate current.

The plate voltage rises sharply to maximum, and this positive-voltage rise at the plate, applied through capacitor C2 to the control grid, drives the grid positive to the point of screen-current saturation. The screen current and the plate voltage remain at maximum while the negative charge on C3, at the suppressor, is leaking off through resistor R3 and the repeller resistor network. As the suppressor potential rises positively past a certain critical value, a pulse of plate current occurs, and the resulting spike of plate voltage drives the control grid negative, causing the cutoff of screen current and returning the screen potential to the maximum positive value. This negative spike of plate voltage occurs as the circuit "flops", transferring the control action of the control grid from the screen back to the plate. Following this charge, the plate voltage starts to decline linearly, and the entire cycle is repeated.

Locked-In Sweep

When the free-running AFC sweep voltage starts to swing more negative, the frequency of the klystron increases. As the beat frequency comes within range of the pass band, positive pulses are developed by V4, and by inversion they appear at the plate of the pulse amplifier, V3, as negative pulses. These pulses are applied to the grid circuit of V2, the AFC sweep generator. Because the low-amplitude negative pulses do not affect the AFC sweep, the repeller voltage continues to decline. When the beat frequency goes past the 30-mc point, the discriminator pulse-output polarity is reversed and the positive pulses are produced at the output of V3. As each positive pulse is applied to capacitor C1, charging current flows rapidly through the electron path provided by the sweep-control tube, V1. As the peak of the pulse passes, the conductivity of V1 is reduced to zero, and C1, discharges slowly through R2. This decline of negative voltage is so slow that as each succeeding pulse occurs, it is integrated with the preceding pulse.

Since the discriminator response changes sharply from the 30-mc crossover point, the corresponding positive pulses from V3 appear in increased amplitude. After several pulses, the bias becomes negative enough to cut off the sweep, which then reverses direction and attempts to rise quickly to a peak value. However, this means that the intermediate frequency begins to decrease, and the positive voltage output of the pulse amplifier begins to lose amplitude, falling to zero at the crossover. The resulting loss of negative bias voltage on the sweep-generator tube again changes the sweep direction, causing it to resume its original slow decline, and the positive pulses from the pulse amplifier again cut off the sweep. When locked in by this sequence of functions, the frequency of the klystron is varied in correct relationship with that of the magnetron, so that the IF beat frequency varies about the crossover point of the discriminator.

The frequency sweep of the klystron with the AFC locked in is restricted by limiting the amplitude of the voltage applied to the klystron, so as to produce only a small frequency deviation. The amplitude is controlled by the rate of slop of the sweep and by the pulse repetition frequency. Reduction in sweep rate (steepness of sweep waveform) represents a smaller change in voltage in a given time.

DELAY SYSTEMS

The term delay systems refers to special control circuits that are used in many electronic systems, particularly in radar sets. These circuits are used for the purpose of delaying a waveform, which, in turn, produces a delayed action. A knowledge of several of the basic circuits will prove helpful in gaining an understanding of the application and operation of delay systems.

Some of the more common types of electronic delay systems are the RC, the phantastron, and the delay line (artificial lines).

PURPOSE AND APPLICATION

The PPI radarscope is a unit that makes use of various applications of different delay systems. Some of these are:

1. CLOSED CENTER OPERATION. In this operation the PPI sweep is started after the magnetron is fired. (See fig. 14-13.) As compared to normal operation, the targets appear

1047 1001

SERVICE A.—The primary purpose of this system is collecting and disseminating aviation weather reports and NOTAM's.

SERVICE C.—The primary purpose of this network is collecting and disseminating domestic synoptic weather information.

SERVICE O.—The Service O system is used primarily for collecting and disseminating international weather information.

MILITARY NETWORKS.—CONUS Meteorological Teletype System (COMET) is an air Force network used to collect military aviation weather observations and pilot reports in the contiguous U.S. and to provide rapid distribution of this information to military users.

The Navy has established six Fleet Weather Centrals which collect weather observations from ships at sea and other Navy weather facilities through the worldwide U. S. Naval Communications System. Navy-originated weather reports may be entered on the FAA weather circuits, COMET, or transmitted via naval communications depending upon their origin, content, and purpose.

Facsimile Networks

Facsimile networks are used to distribute analyses and forecasts in graphic form. Special depictions of other types, such as photographs, also can be made through this distribution method. There are four such networks presently, two operated by the Weather Bureau and one each by the Navy and Air Force. This method may be considered preferable to the teletype; however, present facsimile networks are incapable of handling the volume of aviation weather required.

Local Distribution

Air Controlmen are concerned mostly with weather conditions in the immediate vicinity, and within 50 miles, of the airport. Weather forecasts are used regularly for planning purposes, such as selection of runway, etc. However, air traffic controllers are more concerned with conditions at the present and within the next hour.

Obviously, the amount of weather reports and forecasts discussed to this point, (although necessary for complete weather service) is much more than is actually utilized by the Air Controlman in the performance of routine tasks. Therefore, weather service personnel digest all the weather information and supply the Air Controlman with the needed meteorological information.

This weather information is distributed locally by various methods including TelAutograph (a remote mechanical writing device), interphone, and closed circuit television.

HOURLY AVIATION WEATHER REPORTS

Weather information received from weather service personnel will consist of numerals, symbols, and contractions as used on Teletypewriter networks to describe a large amount of weather information in a small space. The Air Controlman must be able to decode this information for transmission to pilots via radio telephone.

The following section discusses the hourly aviation weather report and gives an explanation of encoding and decoding the symbols used. This explanation is limited to a brief coverage intended to provide the Air Controlman with a working knowledge of aviation weather reports.

CONTENT AND FORMAT OF THE HOURLY AVIATION WEATHER REPORT

Figure 6-1 is an example of an hourly aviation weather report as it would be received on Service A or the Air Force COMET network with minor variations.

LOCATION IDENTIFIERS	"SPECIAL" REPORT	SKY AND CEILING	VISIBILITY WEATHER AND OBSTRUCTION TO VISION	SEA LEVEL PRESSURE	TEMPERATURE AND DEW POINT	WIND	ALTIMETER SETTING	RUNWAY VISUAL RANGE	CODED PIREPS	REMARKS
MKC	S	15⊕M25⊕	4R-K	132	/58/56	/18Ø7	/993/	R16VR13	/⊕55	RBØ5-⊕V⊕

AC.68

Figure 6-1.—Hourly Aviation Weather Report.

Location Identifiers

Three-letter location identifiers identify the station sending the report. All location identifiers are contained in the FAA publication Location Identifiers 7350.1 Series.

Special Report

The letter "S" is used on FAA's Service A to indicate a special report when some significant change in existing weather has occurred and requires immediate dissemination. On the Air Force COMET network, this type of report is identified by the contraction SPUS for Special United States. On all other reports this space is omitted since most other reports fall in the category of hourly weather reports.

Sky and Ceiling

Figures preceding the symbols are heights of clouds in hundreds of feet above the surface rounded off to the nearest reportable value as in table 6-1.

The letter "V" following the cloud height indicates the height is variable. This is a condition in which the value rapidly increases and decreases by one or more reportable values during the period of observation. It is reported only for ceilings less than 3,000 feet. The average of all values secured is used as the cloud height.

Sky cover symbols indicate the amount of sky cover. These symbols are listed on the report in ascending order if more than one layer of clouds or obscuration exists. Table 6-2 lists the sky cover symbols, their meaning, contraction, and explanation.

Table 6-1.—Sky cover height values

Feet	Reportable values (coded in hundreds of feet)	Encoded
5,000 or less	To nearest 100 ft	1,10,50, etc.
5,001 to 10,000	To nearest 500 ft	55,75,100 etc.
Above 10,000	To nearest 1,000 ft	140,180, 200, etc.

A ceiling is either:

1. The height ascribed to the lowest reported opaque broken or overcast layer of clouds or obscuring phenomena aloft, or;
2. The vertical visibility in a surface based pheomena associated with an obscured sky.
3. "Unlimited" when neither of the preceding conditions in 1 or 2 are present.

The letter preceding the height of a ceiling layer of sky cover indicates how the ceiling height was obtained. Specific symbols are employed to denote ceilings obtained by various methods. (See table 6-3.)

Visibility

Visibility is reported in statute miles and fractions thereof to 3 miles, the nearest whole mile to 15 miles, and the nearest 5 miles beyond 15 miles. When the prevailing visibility is judged to exceed 15 miles and the most distant marker is 15 miles or less, but more than 7 miles from the point of observation, the visibility is coded as 15+.

If visibilities of less than 3 miles rapidly increase or decrease by one or more reportable values, the vibibility is followed by the letter "V" for variable.

PREVAILING VISIBILITY.—Prevailing visibility is the greatest visibility which is attained or surpassed throughout at least half of the horizon circle not necessarily continuous. In uniform weather conditions, determination of visibility is relatively simple since it is the same in all directions. In non-uniform weather conditions one aid in determining prevailing visibility is to divide the horizon circle into several sectors, each of which has substantially uniform visibility. (See fig. 6-2.) The prevailing visibility is the visibility entered on the hourly aviation weather report under such conditions.

SECTOR VISIBILITY.—Sector visibility is the visibility within a specified sector of the horizon circle having essentially uniform visibility. Sector visibility is encoded in the remarks section of the hourly aviation weather report when it is different from the prevailing visibility and is less than 3 miles, or when it is considered operationally significant if 3 miles or more. Such remarks include the direction from the station of the sector in which the visibility is different.

CONTROL TOWER OBSERVATIONS AND ACTIONS.—Unless otherwise exempted, certified, qualified Navy Air Controlmen, or otherwise

Table 6-2.—Sky cover symbols.

Symbol	Meaning and contraction	Explanation
○	Clear CLR	0.0 total sky cover. (This symbol is used alone—not in combination with others.)
◐	Scattered layer aloft SCTD	0.1 to 0.5 sky cover at and below level of layer aloft and not classified as "thin."
◑	Broken layer aloft BRKN	0.6 to 0.9 sky cover at and below level of layer aloft and not classified as "thin."
⊕	Overcast layer aloft OVC	1.0 (ten-tenths) sky cover at and below level of layer aloft and not classified as "thin."
X	Obscuration (surface layer)	All of sky is hidden by a surface-based layer; i.e., vertical visibility is restricted by the layer.
-X	Partial obscuration (surface layer)	0.1 or more, but not all of sky is hidden by surface-based layer; i.e., vertical visibility through the layer is not completely restricted.
-◐	THIN SCTD	Sky or higher clouds are visible through the sky cover.
-◑	THIN BRKN	
-⊕	THIN OVC	

Table 6-3.—Ceiling Symbols.

Symbol	Meaning
A	Aircraft.
B	Balloon.
E	Estimated height of noncirriform clouds.
M	Measured.
R	Rawinsonde Balloon or Radar.
W	Indefinite. (Vertical visibility is restricted by surface based obscuration which prevents a determination of the cloud heights.)

authorized tower personnel must report prevailing visibility when the prevailing visibility at the usual point of observation or at the tower level is less than 4 miles. The control tower visibility observations may be used immediately for aircraft operations but must be recorded and forwarded to weather service personnel as soon as practicable. During this condition, control tower personnel must notify weather service as soon as possible when they observe the prevailing visibility at the tower level to decrease to less than 4 miles and change by one or more reportable values.

When the visibility at the usual point of observation is less than 4 miles and the control tower visibility is different but does not qualify as the prevailing visibility, the control tower visibility is encoded in the remarks section of the hourly aviation weather report.

Control tower visibility may be encoded in the remarks section when different from prevailing

10503

10503

visibilities of 4 miles or more when considered operationally significant.

Weather Element Symbols

The following symbols are used to indicate weather elements:

T+ . . . . . Severe thunderstorm
T . . . . . Thunderstorm
R . . . . . Rain
RW . . . . . Rain showers
L . . . . . Drizzle
ZR . . . . . Freezing rain
ZL . . . . . Freezing drizzle
IP . . . . . Ice pellets
IPW . . . . . Ice pellet showers
S . . . . . Snow
SW . . . . . Snow showers
SP . . . . . Snow pellets
SG . . . . . Snow grains
IC . . . . . Ice crystals
A . . . . . Hail

Suffix + to precipitation symbols to indicate heavy intensity,—For light intensity, and -- for "very light." The absence of an intensity symbol indicates "moderate." No intensity is assigned to tornadoes, waterspouts, funnel clouds, hail, or ice crystals, and only moderate or severe is reported for thunderstorms.

Tornadoes, waterspouts, and funnel clouds are always spelled out in full and are followed by letters showing the direction they are bearing from the station and direction toward which it is moving. AN EXAMPLE WOULD BE: TORNADO NW MOVG E.

Precipitation is divided into three classes: liquid, freezing, and frozen. If two different classes of precipitation are present, they are encoded in the above order. If more than one type of precipitation of the same class are present (heavy snow, ice pellets), the one with the greatest intensity is encoded first (S+IP).

Obstructions to Vision Symbols

Hydrometeors (other than precipitation) and lithometeors are called obstructions to vision and are encoded by means of letter symbols if conditions reduce the prevailing visibility to less than 7 miles and the obstruction to vision is occurring at the station. If the visibility is reduced to less than 7 miles by an obstruction at a distance from the station, the phenomena is described in remarks.

The order of encoding, if more than one obstruction is present at the time of the observation, is in order of decreasing predominance. The various symbols follow:

AC.69

Figure 6-2.—Prevailing visibility.

HYDROMETEORS
(water based)

F . . . . . Fog
GF . . . . . Ground fog
IF . . . . . Ice fog
BS . . . . . Blowing snow
BY . . . . . Blowing spray

10504

or RVRNO would appear in place of the normal reading in the hourly aviation weather report.

Coded PIREP's

Pilot reports of heights of bases or tops of sky cover within 20 miles (50 miles for cirriform layers) of the reporting station which are not visible from the station are included in the hourly weather report. These heights are above mean sea level (MSL) as read from the aircraft's altimeter. Figures indicating height preceding the sky cover symbol are the bases of the higher layer not visible from the station. Figures indicating height following the sky cover symbol are the tops of the layer.

EXAMPLE: ⊕ 55/75- ⊕ 1ØØ would mear the top of the reported overcast layer is 5,500 MSL, the base of a higher thin overcast layer is 7,500 MSL, and the top of that layer is 10,000 MSL.

Remarks

Remarks may be work contractions, symbols, and/or plain language where authorized symbols or contractions do not apply. They are used to amplify or explain elements of the report.

Some examples of symbols used in the remarks sections are as follows:

REMARKS	EXPLANATION
K1Ø ⦶	Scattered smoke layer aloft, base 1,000 feet.
BINOVC	Breaks in overcast.
HIR CLDS VSB	Higher clouds visible.
TWRG CU SW	Towering cumulus to the southwest.
CB ALL QUADS	Cumulonimbus all quadrants.
TWR VSBY1 GFDEP 7Ø	Tower visibility 1 mile, ground fog depth 70 feet.
OCNL LTGCC	Occasional lightning cloud to cloud.
HLSTO 1 1/4	Hailstone one and one-quarter inches in diameter.
RWB45	Rain showers began at 45 minutes past the hour.
AE16	Hail ended 16 minutes past the hour.
LTGCG	Lightning, cloud to ground.
LTGIC	Lighting, in clouds.
ICGIC	Icing in clouds.
PRESFR	Pressure falling rapidly.
KDSIPTG	Smoke dissipating.
ALSTG	Altimeter setting.
VSBY N1S4	Visibility north 1 mile, south 4 miles.
T OVHD MOVG SE	Thunderstorm overhead moving southeast.
PRESRR	Pressure rising rapidly.
F INCRG	Fog increasing.
ICGIP	Icing in precipitation.
⦶V⦶	Broken layer in the report is occasionally scattered.
CIG 15V2Ø	Ceiling is varying between 1,500 and 2,000 feet.
VSBY 1V2	Visibility is varying between 1 and 2 miles.
SFC VSBY 1	Surface visibility is 1 mile.
WSHFT ØØØ3	Wind direction shifted at 0003 (GMT).
WSHFT ØØØ3 FROPA	Wind direction shifted at 0003 associated with a frontal passage.

In the remarks section, items extracted from Notice to Airmen (NOTAM's, chapter 3) may be included on FAA Service A hourly aviation weather reports.

All possible contraction for remarks cannot be listed here. For possible changes and additional information, refer to FAA Contractions Handbook 7340.1 Series.

In certain hourly aviation weather reports, additive data is included in remarks such as pressure tendencies, maximum and minimum temperature, cloud groups, etc., intended primarily for use of weather service personnel in preparation of forecast maps.

EXAMPLES OF DECODING HOURLY AVIATION WEATHER REPORTS

1. NCQ -XM3⦶5⊕1 1/2F 1Ø3/63/61/ØØØØ/985/F1. NAS Atlanta, sky partially obscured,

measured ceiling 300 broken, 500 overcast, visibility one and one-half fog, barometric pressure 1010.3 millibars, temperature 63 degrees, dewpoint 61 degrees, wind calm, altimeter 29.85, fog one-tenth.

2. NHZ E46⊕4GFH 1Ø6/55/5Ø/362Ø/983. NAS Burnswick, Maine, estimated ceiling 4600 overcast, visibility 4 ground fog and haze, barometric pressure 1010.6 millibars, temperature 55 degrees, dewpoint 50 degrees, wind 360 degrees at 20 knots, altimeter 29.83.

3. NMM-X/5-⦶3/16GF 623/39/39/Ø1Ø4/ØØ1/ R02VV 1/4/F3. NAS Meridian, sky partially obscured, five hundred thin broken, visibility three-sixteenths ground fog, barometric pressure 962.3 millibars, temperature 39 degrees, dewpoint 39 degrees, wind 010 degrees at 4 knots, altimeter 30.01, runway 2 visibility 1/4 mile, ground fog three tenths.

4. NHK M5⦶2R—F 796/62/59/Ø9Ø3/Ø13/ F4CIG⦶V⦶. NAS Patuxent, measured ceiling 500 broken, visibility 2 very light rain, fog, barometric pressure 979.6 millibars, temperature 62 degrees, dewpoint 59 degrees, wind 090 degrees at 3 knots, altimeter 30.13, fog four tenths, ceiling broken variable scattered.

AVIATION OBSERVATIONS ASSOCIATED WITH THE HOURLY AVIATION WEATHER REPORTS

Aviation weather observations are classified as record (R), special (S), record special (RS), or local (L).

Record Observation (R)

Record observations are normally taken at hourly intervals having a standard time of H + 00 (on the hour). They are the basic observations which supply the weather information for the hourly aviation weather report.

Special Observation (S)

Special weather observations are supplementary to the hourly record observation. They are taken and transmitted as soon as possible after certain significant weather changes have occurred.

Comparing the special to a record observation, the letter S and time of filing is an addition. The sea level pressure, temperature, and dewpoint are omitted.

CRITERIA FOR TAKING SPECIAL OBSERVATIONS.—A special observation is made whenever one or more of the elements listed below have changed in the amounts specified. The amount of change is derived from the last record or special observation.

In any instance when ceiling forms below, decreases to less than, or if below, increases to equal or exceed:

1. 3,000 feet.
2. 1,000 feet.
3. 500 feet.
4. All nationally published minima applicable to the airport.
5. Values established locally because of their significance to aircraft operations.

At all stations, a special observation is made when the sky condition shows clouds below 1,000 feet, and when no clouds were previously reported below this level.

In any instance when prevailing visibility decreases to less than, or if below, increases to equal or exceed:

1. 3 miles.
2. 2 miles.
3. 1 1/2 miles.
4. 1 mile.
5. All nationally published minima applicable to the airport.
6. Values established locally because of their significance to aircraft operations.

A special observation is to be made when a tornado is first observed, disappears from sight, or is reported by the public to have occurred within the last 6 hours.

A special observation is to be made when a thunderstorm begins (thunder is first heard), increases in intensity, or ends (15 minutes after thunder is last heard).

Precipitation causes a special observation to be made when hail begins or ends; freezing precipitation, other than very light, begins, changes intensity, or ends; and ice pellets, other than very light, begins, changes intensity or ends.

Wind and wind shifts are causes for making special observations when the wind suddenly doubles its average speed to more than 26 knots, or when a wind shift occurs.

Tornado or wind special observations may be transmitted as single element specials on the teletype; i.e., the only information transmitted is that which actually requires the special.

These criteria are regarded as minimum requirements for the making of special observations. In addition, any weather situation

that the observe feels is important to safety and efficiency of aircraft operation is reported in a special observation.

Record Special Observation (RS)

If the time of the significant weather changes which constitute a special coincides with the time of the record observation, the two reports are combined; hence the name record special. If this happens, the letter S remains in the report to attract attention to the fact that something special has happened since the last record observation was sent. The date-time group is omitted. The sea-level pressure, temperature, and dewpoint is encoded.

Local Observations (L)

Local observations may be taken at any weather observing station. The elements normally included in a local are ceiling and sky condition, prevailing visibility, weather and obstructions to vision, and remarks (as appropriate).

Local observations are taken when changes in ceiling, visibility, weather, or other elements are significant for local aircraft operations. Definitions or standards of significance are developed locally.

Local observations are taken immediately following an aircraft mishap at or near the station except when notification is delayed or there has been a intervening record observation. Such observations consist of all the elements normally included in a record observation except sea-level pressure. Local arrangements are made to insure that weather service personnel are notified as soon as possible of all aircraft mishaps.

Local observations may also be requested by appropriate personnel when required for purposes other than those listed in the preceding paragraphs.

PILOT'S REPORTS (PIREP'S)

Pilot's reports of meteorological phenomena encountered in flight are called PIREP's. These reports are an extremely valuable source of weather information often not available otherwise. PIREP's are reports of the weather along the actual routes the pilots are flying. Reports concerning such things as cloud tops, icing levels, etc., are extremely valuable in planning and executing flights. All Air Controlmen are expected to cooperate to the fullest extent possible in securing and disseminating PIREP's. In order to do this, it is necessary to learn what information is included in the PIREP's and learn their encoding and decoding.

PIREP's are encoded and disseminated locally and on weather communications networks. These PIREP's are in addition to the Pilot Reports of bases and tops of clouds included in the remarks section of the hourly aviation weather report.

PIREP FORMAT

Arrangement of the elements of a PIREP is as follows:

1. Station identification.
2. The term PIREP
3. Location or extent of phenomena relative to an observing station or other nationally known point.
4. Time (GMT) of pilot's observation, if known.
5. Phenomena reported.
6. Altitude of phenomena in hundreds of feet above mean sea level (MSL).
7. Type of aircraft in reports of turbulence, condensation trails, electrical discharge, and icing only; if unknown, the contraction ACFT UNKN would be inserted.

EXAMPLES OF PIREP'S

The pilot of a P2 between Richmond, Va., and Washington, D.C., reports to Washington that at 1620 EST his aircraft experienced an electrical discharge 20 miles south of Washington at an altitude of 5,000 MSL. This would be encoded as follows:

DCA PIREP 20 S

DCA 212Ø DISCHARGE 5Ø P2

The contraction TURBC preceded by an indication of the intensity is used to encode turbulence as follows:

LGT TURBC . . . . Light turbulence
MDT TURBC . . . . Moderate turbulence
SVR TURBC . . . . Severe turbulence
EXTRM TURBC . . Extreme turbulence

10508

When clear air turbulence is reported, the contraction CAT is used in place of TURBC.

A pilot reports to Atlanta, Ga., that his C-54 encountered extreme turbulence at 2330 CST, 10 miles northeast of Knoxville, Tenn., at 6,000 MSL. This would be encoded as follows:

ATL PIREP 10 NE TYS

053Ø EXTRM TURBC 6Ø C54

At 1215 CST, the pilot of a P3 reports to Madison, Wis., a 72-knot wind from 240 degrees, 20 miles southeast of the station, at 8,500 MSL. This would be encoded as follows:

MSN PIREP 2Ø SE MSN

1815 WND 24Ø 72 KT 85

The contraction ICG preceded by an indication of its intensity and type, (if known), is used to encode icing conditions as follows:

TRACE ICG . . . . Slow rate of accumulation not hazardous unless encountered for extended periods.

LGT RIME ICG . . . . Rate of accumulation may become a problem with prolonged encounter. Usually not a problem if deicing equipment used.

MDT ICG . . . . Rate of accumulation is such that brief encounters may become hazardous and use of deicing equipment or diversion necessary.

SVR ICG . . . . Rate of accumulation is such that deicing equipment fails to control the hazard and immediate diversion is necessary.

AT 0925Z the pilot of an F-4 reports to Burbank radio an encounter of severe clear icing between 10,000 and 11,500 feet over mountains north of Burbank. This would be encoded as follows:

BUR PIREP MTNS N BUR

Ø925 SVR CLR ICG 1ØØ-115 F4

Pilots reports of tornadoes, funnel clouds or waterspouts, severe or extreme turbulence, hail, and severe icing must be given immediate local desimination.

WEATHER ADVISORIES

FLIGHT ADVISORIES

Flight Advisories are prepared by the Weather Bureau FAWS Centers and contain information of weather developments in their areas of responsibility that are considered to be potentially hazardous to aircraft in flight. The advisories are issued in two categories, SIGMET's (Significant Meteorological Information), and AIRMET's (Airman's Meteorological Information).

Significant Meteorological Information

A SIGMET advisory will be issued concerning weather of such severity as to be potentially hazardous to transport category and other aircraft for the following weather developments:

1. Tornadoes.
2. Lines of thunderstorms (squall lines).
3. Hail, 3/4 inch or more in diameter.
4. Servere and extreme turbulence.
5. Severe icing.
6. Widespread dust storms/sand storms lowering visibility to less than 2 miles.

Airmen's Meteorological Information

AIRMET advisories will be issued concerning weather of such a degree as to be potentially hazardous to light aircraft, but not necessarily to transport category aircraft for the following weather developments.

1. Moderate icing.
2. Moderate turbulence.
3. The initial onset of phenomena producing areas of visibility less than 2 miles with ceilings less than 1,000 feet, including mountain ridges and passes.
4. Winds of 40 knots or more within 2,000 feet of the surface.

Flight advisories are transmitted on Service A.

HURRICANE ADVISORIES (WH)

Huricane advisories are written in plain language and are usually transmitted four times daily when a hurricane is threatening an area. The complete and detailed message is filed on Service C to describe the location, extent, intensity, and movement of the storm, as well as to forecast these general features of the storm.

COLLECTIVE OUTLOOKS (AC)

The AC is a daily outlook for thunderstorm activity in the U.S. and is transmitted on Service

A. These advisories are transmitted only during the appropriate season by the National Severe Storm Forecast Center (NSSFC) at Kansas City. This plain language outlook describes the prospects of severe weather for the next 24 hours in general terms.

SEVERE WEATHER FORECASTS (WW)

WW's are severe weather forecasts issued on Service A by the (NSSFC) center at Kansas City as required by severe weather conditions. Their chief use is in preflight briefing, but tower and ARTCC personnel also use them when their area of concern is affected.

RADAR WEATHER REPORTS (SD) AND RADAR WEATHER REPORT SUMMARIES (SD-1)

Radar Weather Reports (SD) (S for storm, D for detection) initiate mainly from Weather Bureau stations, but are supplemented by reports from military radar stations. SD's contain information on intensity and tendencies, etc., of storms. They are transmitted on Service A at irregular intervals.

Radar Weather Report Summaries (SD-1) are prepared by the Weather Bureau Radar Unit at Kansas City at hourly intervals for transmission on Service A. The summary is divided into broad geographical areas of the U.S. depending upon the degree of storm activity at the time the SD-1 is prepared.

PHRASEOLOGY FOR WEATHER REPORT ITEMS

AC's are continuously required to transmit weather information to pilots via radio; for example, to departing or arriving aircraft or in response to special pilot requests. The following list includes examples of phraseology which coincide with FAA voice procedure for broadcasting aviation weather reports to which pilots listen frequently. Its purpose is to enhance standardization of transmitting weather information.

1. State the height and character of sky coverage data as follows:

a. In the same order of ascending height in which they appear in the weather report.

b. Do not say the word "clouds."

c. Announce ceiling height designators as follows:

CODED	SPOKEN
A	PILOT REPORTS CEILING
E	ESTIMATED CEILING
B	BALLOON CEILING
M or R	MEASURED CEILING
W	INDEFININTE CEILING

d. State heights in hundreds and/or thousands of feet.

CODED	SPOKEN
3	THREE HUNDRED
18	ONE THOUSAND EIGHT HUNDRED
2ØØ	TWO ZERO THOUSAND

e. Announce cloud symbols as follows:

CODED	SPOKEN
○	CLEAR
⦶	SCATTERED
⦷	BROKEN
⊕	OVERCAST

f. When a dash precedes a cloud symbol, say the word THIN.

CODED	SPOKEN
7 -⦷	SEVEN HUNDRED THIN BROKEN

g. Announce a ceiling height indicated by the figure "0" as ZERO.

h. Announce a condition indicated by "X" or "-X" as:

CODED	SPOKEN
X	SKY OBSCURED
-X	SKY PARTIALLY OBSCURED

i. Announce sky and ceiling conditions (not all possible combinations of phenomena

Figure 14-13. —Normal and closed center operation.

to be moving in toward the center of the scope, hence the name closed center. This is used to eliminate the ground or sea return in the center of the scope. Also, it extends the range of the radar by the amount of delay that is used.

2. OPEN CENTER OPERATION. The magnetron fires after the sweep has started. (See fig. 14-14.) As compared to normal operation, the targets appear to be moving toward the outer edge of the scope. This action moves close-in targets toward the outer edge of the scope where they occupy more space on the scope face. This spreads the target over more area and improves target resolution. The effective range on this sweep is reduced by the amount of delay used.

3. EXPANDED DELAY SWEEP. The start of the sweep is delayed for a number of miles. (See fig. 14-14.) A much faster sweep speed

Figure 14-14. —Open center and expanded delay operation.

are included) in accordance with the following:

CODED	SPOKEN
-XM1ØⒹ5ØⒹ	SKY PARTIALLY OBSCURED, MEASURED CEILING ONE THOUSAND BROKEN, FIVE THOUSAND BROKEN.
20ⒹE30Ⓓ 250Ⓓ	TWO THOUSAND SCATTERED, ESTIMATED CEILING THREE THOUSAND BROKEN, TWO FIVE THOUSAND BROKEN.
M1ØⒹ5ØⒹ 3ØØ⊕	MEASURED CEILING ONE THOUSAND BROKEN, FIVE THOUSAND BROKEN, THREE ZERO THOUSAND OVERCAST.
1ØⒹ5ØⒹ	ONE THOUSAND SCATTERED, FIVE THOUSAND SCATTERED.
5ⒹW15X	FIVE HUNDRED SCATTERED, INDEFINITE CEILING ONE THOUSAND FIVE HUNDRED, SKY OBSCURED.
-XM5⊕	SKY PARTIALLY OBSCURED, MEASURED CEILING FIVE HUNDRED OVERCAST.
-X5-Ⓓ1Ø-Ⓓ 5Ø-⊕	SKY PARTIALLY OBSCURED, FIVE HUNDRED THIN BROKEN, ONE THOUSAND THIN BROKEN, FIVE THOUSAND THIN OVERCAST.
1Ø-ⒹE2ØⒹ 45Ø⊕	ONE THOUSAND THIN SCATTERED, ESTIMATED CEILING TWO THOUSAND BROKEN, FOUR FIVE THOUSAND OVERCAST.
2ØⒹA25Ø⊕	TWO THOUSAND SCATTERED, PILOT REPORTS CEILING TWO FIVE THOUSAND OVERCAST.

2. Announce prevailing visibility immediately following sky conditions. This element is reported in statute miles at land stations and in nautical miles on ships and ocean station vessels (OSV).

NOTE: When visibility is less than 3 miles and variable, this information is reported in remarks.

Announce prevailing visibility in accordance with the following examples:

CODED	SPOKEN
1/16	VISIBILITY ONE-SIXTEENTH
1/8	VISIBILITY ONE-EIGHTH
3/4	VISIBILITY THREE-QUARTERS
1 1/2V	VISIBILITY ONE AND ONE-HALF VARIABLE
6	VISIBILITY SIX
15+	VISIBILITY MORE THAN ONE FIVE

3. If atmosphere phenomena and obstructions to vision appear in a weather report, announce these conditions following the prevailing visibility, as follows:

a. Atmospheric phenomena:

CODED	SPOKEN
T	THUNDERSTORM
R	RAIN
RW	RAIN SHOWERS
ZR	FREEZING RAIN
L	DRIZZLE
ZL	FREEZING DRIZZLE
IP	ICE PELLETS
IPW	ICE PELLET SHOWERS
S	SNOW
SW	SNOW SHOWERS
SP	SNOW PELLETS
SG	SNOW GRAINS
IC	ICE CRYSTALS
A	HAIL

b. Announce HEAVY, MODERATE, LIGHT or VERY LIGHT when a plus sign (+), no sign, one dash (-), or two dashes (--) respectively are suffixed to the precipitation symbol, except announce "T" as THUNDERSTORM and "T+" as SEVERE THUNDERSTORM. No suffix is attached to hail or ice crystals regardless of the intensity.

c. Obstructions to vision:

CODED	SPOKEN
F	FOG
GF	GROUND FOG

10511

CODED	SPOKEN
IF	ICE FOG
BD	BLOWING DUST
BN	BLOWING SAND
BS	BLOWING SNOW
BY	BLOWING SPRAY
H	HAZE
K	SMOKE
D	DUST

4. Omit sea-level pressure from the broadcast. Give sea-level pressure in millibars only in response to a specific request from a pilot.

5. Announce temperature and dewpoint in accordance with the following:

a. In two or three figures in degrees Fahrenheit.

b. Below zero Fahrenheit values by prefixing the temperature with the word MINUS.

CODED	SPOKEN
37/36	TEMPERATURE THREE SEVEN, DEWPOINT THREE SIX
1Ø4/99	TEMPERATURE ONE ZERO FOUR, DEWPOINT NINER NINER
-2/-3	TEMPERATURE MINUS TWO, DEWPOINT MINUS THREE

6. Announce current local wind direction and speed as determined from the instruments in the console as follows:

a. State wind direction in tens of degrees (in terms of the magnetic compass), using three digits.

b. Omit the words MAGNETIC, TRUE, or KNOTS.

c. Announce a north wind as THREE SIX ZERO.

d. Read other than local wind direction as it appears in the report; i.e., TRUE rather than MAGNETIC.

CODED	SPOKEN
3514	WIND THREE FIVE ZERO DEGREES AT ONE FOUR

e. Announce wind speed in knots. If it is estimated, state: WIND (direction), ESTIMATED (speed).

7. Announce each of the four digits of the altimeter setting by adding as the first digit the figure "2" or "3," as appropriate, and using values obtained from altimeter setting indicator instruments, where available.

CODED	SPOKEN
996	ALTIMETER TWO NINER NINER SIX
Ø1Ø	ALTIMETER THREE ZERO ONE ZERO

8. Announce RVV and RVR as follows:

a. State runway visibility (RVV) in the same manner as prevailing visibility.

CODED	SPOKEN
R4VV1/4V1	RUNWAY FOUR VISIBILITY ONE QUARTER VARIABLE TO ONE
R36VV1 1/2+	RUNWAY THREE SIX VISIBILITY MORE THAN ONE AND ONE HALF
RVVNO	RUNWAY VISIBILITY NOT AVAILABLE

b. Announce runway visual range (RVR) at the location of origin only, in hundreds or thousands of feet. When the readout reports 1,000 --, announce LESS THAN ONE THOUSAND FEET.

CODED	SPOKEN
R18VR4Ø	RUNWAY ONE EIGHT VISUAL RANGE FOUR THOUSAND FEET
R16VR1Ø	RUNWAY ONE SIX VISUAL RANGE LESS THAN ONE THOUSAND FEET
RVRNO	RUNWAY VISUAL RANGE NOT AVAILABLE

9. Announce remarks and NOTAM's included in weather reports when of interest to pilots. Do not include additive data intended primarily for the preparation of forecast maps. Announce as follows:

a. State the variable prevailing visibility in accordance with the following:

CODED	SPOKEN
VSBY 1V2	VISIBILITY VARIABLE BETWEEN ONE AND TWO

10512

b. State sector visibility in the same manner as prevailing visibility.

CODED	SPOKEN
VSBY NE3 SE2 1/2 SW2	VISIBILITY NORTHEAST THREE, SOUTHEAST TWO AND ONE-HALF, SOUTHWEST TWO

10. Announce remarks in accordance with the following:

CODED	SPOKEN
PTCHS GF W N E	PATCHES OF GROUND FOG WEST, NORTH, AND EAST
TWR VSBY5 GF DEP 3Ø	TOWER VISIBILITY FIVE, GROUND FOG THREE ZERO FEET DEEP
22Ø⊙28Ø FEW AC OVR RDG SW	BROKEN CLOUDS REPORTED AT TWO TWO THOUSAND, TOPS AT TWO EIGHT THOUSAND, FEW ALTOCUMULUS OVER RIDGE SOUTHWEST
TOVHD MOVG E B28FQT LTGCG	THUNDERSTORM OVERHEAD MOVING EAST. (TIME BEGUN—H + 28—NOT SPOKEN). FREQUENT LIGHTNING CLOUD TO GROUND
⦶V⦶	SCATTERED LAYER VARIABLE BROKEN
TCU NW	TOWERING CUMULUS NORTHWEST
K1Ø⦶	SMOKE LAYER ONE THOUSAND
RWU E	RAIN SHOWERS OF UNKNOWN INTENSITY EAST
SN0INCR5	SNOW INCREASED DURING PAST HOUR FIVE INCHES
S-OCNLY S+	LIGHT SNOW, OCCASIONALLY HEAVY SNOW

CHAPTER 7

BASIC AIR NAVIGATION

Air navigation has borrowed and adapted many of the instruments, practices, and procedures of marine navigation; thus, fundamental knowledge and skills are the same for marine and air navigation. It will be necessary for the Air Controlman to understand some of the problems encountered by pilots in planning and completing a successful flight. Also, a sound understanding of the basic theories of navigation is of importance to the Air Controlman to give him the required know-how in the daily application of his duties.

This chapter is intended to familiarize the AC with the fundamentals of air navigation and should give him the confidence necessary when called on to render assistance to pilots.

BASIC CONCEPTS OF AIR NAVIGATION

Any purposeful movement in the universe ultimately involves an intention to proceed to a definite point, and navigation is the business of proceeding in such a manner as to arrive at that point. Air navigation is defined, formally, as the process of directing the movement of an aircraft from one point to another. The function of air navigation is primarily to determine the direction necessary to accomplish the intended flight, locate positions, and measure distance and time as means to that end.

Position is a point defined by stated or implied coordinates. This term is frequently qualified by such adjectives as estimated, dead reckoning, no wind, etc., whose meanings will be explained later in this chapter. But however qualified, the word position always refers to some place that can be identified. One of the basic problems of the navigator is that of fixing his position; unless he knows where he is, he frequently cannot know how to direct the movement of the aircraft to its intended destination.

Direction is the position of one point in space relative to another without reference to the distance between them. Direction may be either 3-dimensional or 2-dimensional, the horizontal being the usual plane of 2-dimensional direction. For example, the direction of San Francisco from New York is approximately west (2-dimensional); while the direction of an aircraft from an observer on the ground may be west and 20 degrees above the horizontal (3-dimensional). Direction is not itself an angle (that is, the direction east) but it is often measured in terms of its angular distance from a reference direction.

Distance is the spatial separation between two points and is measured by the length of a line joining them. This seems understandable enough. Suppose, however, that the two points are on opposite sides of a baseball. How is the line to be drawn? Does it run through the center of the ball, or around the surface? If around the ball, what path does it follow? The term distance as used in navigation must be qualified to indicate how the distance is to be measured. The shortest distance on the earth's surface from San Diego to Sydney, Australia, is 6,530 miles, but via Honolulu and Guam, a frequently used route, it is 8,602 miles. And, furthermore, the length of the chosen line could be expressed in various units, as miles, kilometers, or yards.

Time has many definitions, but those used in navigation consist mainly of two: the hour of the day, and an elapsed interval. The first is used to designate a definite instant, as takeoff time is 0215. The second definition is used to indicate an interval, as time of flight, 2 hours 15 minutes.

A map or a chart of the earth's surface is the primary instrument used in air navigation. Without a chart it would be impossible to navigate. Therefore, it is important to understand certain known facts indicated on these charts

about the earth's surface. Some of these will be familiar, others may not. To insure that all are known, let us start from the very beginning and review the pertinent facts.

The earth resembles a spinning ball. The imaginary line about which the earth rotates is called the axis of the earth. The ends of the axis are called the North Geographic Pole and the South Geographic Pole.

Although most people think of it as such, the earth is not a true sphere. A sphere is a body whose surface is equidistant from a point within, known as the center. Any line which passes from one side of a sphere through the center to the other side is a diameter of the sphere. Obviously, one diameter is equal to every other diameter.

The earth is slightly flattened at the poles. This causes its axis to be about 26 miles shorter than its greatest diameter. This difference, however, is only about 0.3 percent of the diameter. Therefore, for the purposes of navigation, the earth may be considered a true sphere.

POSITION

It is necessary to have a system for designating any position on the surface of the earth. Sometimes we may simply say that the aircraft is 10 miles south of San Diego or that its destination is the municipal airport. Such designations may be clear and simple enough, but they would be useless in designating the aircraft's position while crossing the Atlantic Ocean. It would not be sufficient to say that the aircraft was in the middle of the Atlantic or 3 miles south of an iceberg. What is needed is a universal method of expressing position without regard to nearby geographic features.

To tell a stranger the location of a restaurant in Chicago, one might say that it is at the corner of 2nd Street and 3rd Avenue. This definitely tells him the location, as there is only one place in all the city at which 2nd Street and 3rd Avenue cross. You might also tell him that the restaurant is 2 blocks north of Main Street and 3 blocks east of Broadway. This is just as definite. Quantities which give position with respect to two reference lines are called coordinates. Thus, "2 blocks north" and "3 blocks east" are the coordinates of the restaurant relative to Main Street and Broadway.

Positions on the earth may be given by a similar system of coordinates. However, since there are no natural lines on the earth to serve as reference lines, it is necessary to use imaginary lines.

Straight lines are usually the most convenient with which to work. However, straight lines cannot be drawn on a curved surface. On a sphere, the most convenient reference line is a circle.

Circles on a Sphere

If a sphere is cut straight through the center, the resulting cut edges are circles. Thus, the intersection of a plane with a sphere forms a circle. If the plane passes through the center of the sphere, dividing it in half, the circle formed is a great circle. (See fig. 7-1.) A great circle is the largest circle which can be drawn on a given sphere. Any circle, other

AC.71

Figure 7-1.—Circles on a sphere.

10515

than a great circle, no matter how large, is called a small circle. (See fig. 7-1.) The plane of a small circle, of course, does not pass through the center of the sphere, and hence does not divide it into equal halves.

Segments of circles or arcs are measured in degrees, minutes, and seconds. A circle contains 360° of arc. Each degree (°) is 1/360 of the circumference of a circle. Thus, if any circle is divided into 360 equal arcs, each arc is 1° in length, regardless of the size of the circle. A minute (') is 1/60 of 1°—a second ('') is 1/60 of 1'.

Notice in figure 7-2 that if a straight line is drawn from each end of an arc to the center of the circle, the two lines meet to form an angle at the center. This angle is subtended by the arc. Angles, like arcs, are measured in degrees, minutes, and seconds. The angle at the center of a circle (fig. 7-2) always contains the same number of degrees, minutes, and seconds as the arc which subtends it.

Reference Lines on the Earth

As stated earlier in this chapter, circles make the best reference lines for designating position on a sphere. The question is where to draw the circles. A sphere is a continuous surface without beginning or end, and on the earth the only distinctive natural geometric line is its axis, which is different from every other diameter, by about 26 miles, as previously stated. Thus, the geographic poles are distinctive points on the earth. The geographic poles are used as the central points for one set of reference circles. The most important circle of this set is the Equator.

The Equator is the great circle halfway between the poles. Since the poles are 180°, or half a circle apart, every point on the Equator is 90° from each pole. The plane of the Equator is perpendicular to the earth's axis. The Equator divides the earth into a northern and southern hemisphere, and it is important to remember that the Equator serves as a reference line for denoting north and south latitude.

Any small circle on the earth whose plane is parallel with the plane of the Equator is called a parallel of latitude, or simply a parallel. Each parallel is everywhere equidistant from the poles, from the Equator, and from every other parallel. Thus, the parallels and the Equator are concentric about the polar axis. (See fig. 7-3.)

Every point on the earth has a parallel passing through it. However, only a few of these parallels are shown on the globe; the globe would be solid black if they were all shown. Each parallel is designated by its angular distance north or south of the Equator; that is, toward the North or South Pole, as the case might be.

Points east or west on the earth are located by reference to a meridian of longitude, or simply a meridian. (See fig. 7-4.) Instead of

AC.72

Figure 7-2.—The angle at the center is equal to the arc.

AC.73

Figure 7-3.—Parallels of latitude.

10516

AC.74

Figure 7-4.—Meridians of longitude.

using small circles as in the case with latitude, the longitude system is based on great circles passing through the poles. These great circles are divided in half by the poles, and are farthest apart at the Equator. Each half of the circle is assigned a value east or west.

The prime meridian is the meridian whose plane passes through the Observatory at Greenwich, England, which has been adopted as an origin for the measurement of longitude. This meridian is also referred to as Greenwich meridian, and serves as our second reference line. (See fig. 7-4.)

Latitude and Longitude

The parallels and meridians intersect at right angles to form a grid system comparable to the intersecting streets of a city. You can designate any position in a city by naming the streets which pass through it. Likewise, you can designate any point on the earth by naming the parallel and meridian which pass through it. Thus, the 29°45'N parallel and the 95°22'W meridian together designate Houston, Texas. (See fig. 7-5.) Any point on the earth can be designated by giving its coordinates relative to the Equator and Greenwich meridian. These coordinates are called latitude and longitude.

The latitude of a point is its angular distance north or south of the Equator, measured in the plane of the meridian. It is measured from 0° at the Equator, north to 90° at the North Pole, and south to 90° at the South Pole.

The longitude of a point is its angular distance east or west of the prime meridian, measured in the plane of the Equator or of a parallel. Longitude is measured from 0° to 180° east and from 0° to 180° west from the prime meridian. In giving the coordinates of a place, give latitude first, then longitude; i.e., 29°45'N, 95°22'W. Note again in figure 7-5 how this was illustrated.

Each parallel and meridian is named according to its angular distance from the Equator or the prime meridian. Keep in mind, however, that a meridian of longitude is a line; whereas longitude is an angle. Likewise, a

AC.75

Figure 7-5.—Position designated by coordinates.

10517

parallel of latitude is a line; whereas latitude is an angle.

DL and DLo

The difference of latitude (DL) between two points is the angular distance between the parallels which pass through these points. Thus, it is the arc of any meridian between these parallels. If both points are on the same side of the Equator, the smaller latitude is subtracted from the larger. Therefore, the DL between 20° N at point A and 40° N at point B is 20°. (See fig. 7-6.) If the two points are on opposite sides of the Equator, the two latitudes are added. In figure 7-6, the latitude at A is 20° N. If the latitude at C is 15°S, the difference of latitude between A and C is 35°.

Similarly, the difference of longitude (DLo) between any two points is the angular distance between their meridians. If both points are in east longitude or if both are in west longitude, the smaller longitude is subtracted from the larger. Therefore the DLo between 85° E at point A and 125° E at point B is 40°. (See fig. 7-7.) If one point is in east longitude and the other west longitude, the two longitudes are added. If their sum is greater than 180°, this figure is subtracted from 360°. Thus, the DLo

AC.76

Figure 7-6.—Difference of latitude.

AC.77

Figure 7-7.—Difference of longitude.

of 125°E at point B and 135°W at point C is 100°.

DIRECTION

To walk across the street to a friend's house, one merely glances at the house and starts walking in that direction. But to fly from Norfolk to Jacksonville, this simple method cannot be used. The direction must be obtained in some other manner, usually from a chart. The pilot keeps the aircraft headed in the right direction in order to reach Jacksonville. From this example, it can easily be seen that direction is important in navigation, and that some system must be used for expressing the direction from any point to any other point.

North is the direction of the North Pole from any point on the earth, south is the direction of the South Pole; and as one faces north, east is to the right and west is to the left. These are only four of an infinite number of possible directions. In navigation, the system of designating direction permits more exact locating of positions.

Direction is expressed as an angle measured clockwise from north. At any position, imagine a circle whose circumference is divided into 360 equal units. If the divisions are numbered clockwise from north, they indicate true directions from the central point. Such a circle is called a compass rose. The direction of north is 000° or 360°, east is 090°, south is 180°, and west is 270°. In figure 7-8, the direction of B from A is the angle measured clockwise from north to the line AB. (Direction is navigationally defined as a point on the horizon toward which a craft is moving, and it is essentially a line.) Line AB is the angle between the meridian and AB and the direction of B is 045°. Likewise, the direction of C from A is 100° and the direction of D from A is 260°. (See fig. 7-8.)

AC.78

Figure 7-8.—Direction.

It will be helpful to think of directions as angles. Practice estimating the directions of lines by dividing a compass rose into quarters or quadrants, and note which directions fall into each quadrant. Unless there is an arrow, or some device, to show which way a line points, the line has two directions differing by 180°. Later in this chapter, it will be seen why it is important to learn to estimate direction now and avoid making a 180° error. In figure 7-8, the direction of B from A is 045°.

Magnetic Compass

As its name implies, the magnetic compass utilizes the force known as magnetism. The earth itself has a magnetized core, two magnetic poles, and lines of force that form a magnetic field. Like any other magnet, the earth also has a north magnetic pole and a south magnetic pole. Each is about 1,400 miles away from its corresponding geographic pole. Although they are placed at specific geographic sites on magnetic charts, the locations of the magnetic poles change slightly from time to time.

As in any magnet, lines of force run between the north and south magnetic poles of the earth. Its magnetic field affects any magnetic substance; and as a result, a freely suspended magnetic bar or needle will tend to aline itself with the earth's lines of force. These lines of force are similar to meridians and are called magnetic meridians.

The magnetic compass is simple in construction. It contains two steel magnetized needles mounted on a float. A compass card is attached around the float. The needles are parallel, with their north-seeking ends pointed in the same direction. The compass card has letters for cardinal headings (N, E, S, W). Each 30° is represented by a number, from which the last zero is omitted. Between these numbers, the card is graduated for each 5°.

Heading Determined by a Compass

Compasses are used for determining heading, which is the angle measured clockwise

10519

from a reference point to the longitudinal axis of the aircraft.

Notice in figure 7-9 that no specific reference point is mentioned. The reference point could be one of several. If the angle is expressed with relation to true north, it is known as TRUE HEADING (TH). If it is measured from magnetic north, it is called MAGNETIC HEADING (MH). Theoretically, it might be measured from compass north, and the term used would be COMPASS HEADING (CH). In each case, the angle is measured in a clockwise direction from the north reference to the longitudinal axis of the aircraft. It is important to designate which reference was used since all of them do not have the same value as shown in figure 7-9. This is accomplished by designating the reference by one of the terms true, magnetic, or compass.

Variation

It has already been stated that when a magnetized needle is influenced by the earth's magnetic field, the direction it points is magnetic north (MN), and the direction of the north geographic pole is called true north (TN). The angle between magnetic north and true north is termed the variation. Variation differs at different points on the earth. If the needle points to true north, then magnetic north and true north coincide and the variation is zero. When the needle points east of true north, the variation is said to be east; if the needle points west of true north, the variation is called west. (See fig. 7-10.)

AC.79

Figure 7-9.—Reference points in determining headings.

Note that most charts have information concerning lines of variation. The lines that connect points of equal variation are called isogonic lines. A line which connects points of zero variation is known as an agonic line. Usually, aircraft courses are plotted from a true north reference rather than a magnetic north reference simply because the grid on conventional charts is designed using true north as a reference. As the compass needle is deflected east or west of true north by an angular amount known as variation, a correction must be applied to the true heading in order to obtain magnetic headings. This amount of correction is found on the chart by noting the position of the aircraft in relation to the nearest isogonic line.

Deviation

It has been brought out that variation is caused by magnetic forces outside the aircraft. However, a compass is affected by ALL magnetic fields. A piece of iron close to a compass needle tends to deflect it from magnetic north. Whenever an electric current passes through a wire, a magnetic field is set up around the wire. The combined effect of all the magnetic fields within the aircraft (due to its metal structure (metal containing iron), and operation of electrical and electronic equipment) causes an error in the compass known as deviation.

To understand deviation better, assume that the compass needle always points directly to a nonexistent compass north pole. The direction in which the compass needle points is known as compass north. Compass directions may be expressed relative to compass north just as true directions are expressed relative to true north and magnetic directions are expressed in relation to magnetic north.

Although the compass needle primarily seeks alinement with the earth's magnetic field, deviation will vary as the aircraft changes heading. The metal structure and electrical devices naturally turn with the aircraft, creating a different alinement relationship. As this relationship to the compass needle changes, deviation also changes.

Since deviation may vary with each heading, deviation must be determined for each heading that differs by approximately 15° from the

10520

is used but sweep amplitude remains the same. This causes the distant returns to be spread so they can be distinguished from each other. The disadvantage is that nothing can be seen on the scope prior to the time the sweep is started. (All close-in targets are obscured).

RC DELAY SYSTEM

This system may be used for open or closed center operation. It is used in some radar systems to permit the sweep to become linear before the transmitter is fired. The PPI sweep starts at time zero; the RC delay causes the transmitter to be fired later, at a fixed time, after the sweep has become linear. (Refer to fig. 14-15.)

Since the grid is connected to a positive voltage, V1 normally conducts heavily. Thus, plate voltage is low and C2 is charged to this low voltage. The input to V1 is derived from the multivibrator timer and is a negative square wave. The leading edge of this square wave is time zero, and it is at this time that the sweep generator is triggered. The leading edge of this square wave cuts off V1 which was normally conducting. Plate voltage of V1 cannot rise instantly because of the time required to charge C2. Although C2 charges at an RC rate, during the first 10 percent of time the change in voltage is linear. V2 is normally cut off by a voltage divider network in the grid circuit which places a minus 19.5 volts on the grid. The linear change in voltage at the plate of V1 is coupled to the grid of V2 causing it to go positive and to overcome its bias. The delay is a function of the bias applied to the grid of V2 and the rate of charge of C2. When the bias is overcome, V2 conducts and the blocking oscillator action produces a pulse output. A positive pulse output may be taken from the cathode and a negative pulse from across the plate load resistor. The blocking oscillator action in the grid circuit charges both C2 and C3 in a negative direction. This causes the plate voltage of V1 to decrease and keeps V1 from again triggering V2 immediately. Before C2 can again become positively charged to the point that it can trigger V2, the short RC in the grid of V1 has allowed V1 to conduct. Therefore, the circuit has returned to the static condition of V1 conducting heavily and V2 cutoff.

The output of V2 can be used to start the sweep and other timing circuits such as range mark generators.

Figure 14-15.—RC delay circuit

PHANTASTRON DELAY SYSTEM

A phantastron delay system may be used to produce a variable delay over the PPI range. In order to provide a delay over most of the full range of the PPI, it is necessary to use a cathode follower with the phantastron. (See fig. 14-16.)

The phantastron is triggered simultaneously with the firing of the transmitter. The trigger input is applied to the cathode of V1 and the output of the phantastron is taken from the screen of V2. This output is a square wave that goes positive at the start of the delay and negative at the end. The output of the phantastron is applied to the trigger amplifier V4A. The end of the delay appears as a positive pulse at the plate of the amplifier. This pulse is coupled to the grid of the blocking oscillator V4B. This oscillator is biased negatively by the voltage divider network R3, R4, and a negative 105 volts; thus, it is normally cut off. Blocking oscillator action is initiated by the positive pulse from the trigger amplifier. The delayed sweep trigger is taken from the plate of the blocking oscillator V4B. A delay marker is taken from the cathode of the same tube. This marker appears as a movable range marker or ring on

AC.80

Figure 7-10.—Angles of variation.

previous heading. This is accomplished by a process called swinging the compass. This may be done either in the air or on the ground. The most common method on the ground makes use of a large compass rose, on a concrete area, with magnetic headings inscribed at 15° intervals. Swinging the compass essentially consists of obtaining a compass reading from a known magnetic heading. If the compass reading is greater than the magnetic heading, that is, if the compass reads too high, the deviation is east, and if the compass reads lower than the magnetic heading, the deviation is west. The values of deviation are then recorded on a suitable deviation card and placed in the cockpit of the aircraft.

Applying Variation and Deviation

In navigation it is necessary to be able to change a compass heading to a corresponding true heading, or to start with a true heading and determine the equivalent compass heading. For example, we may start with a compass heading. By applying deviation to this compass heading we obtain the magnetic heading. Variation applied to this magnetic heading gives us the true heading. To help solve a problem of this nature, the following formula is used:

COMPASS ± DEVIATION = MAGNETIC
MAGNETIC ± VARIATION = TRUE HEADING

In going the other way, the same procedure is followed. If we know the true heading that is to be flown, it is necessary to find the compass heading to steer in order to maintain this true heading. In this case it is customary to proceed as follows:

TRUE ± VARIATION = MAGNETIC
MAGNETIC ± DEVIATION = COMPASS HEADING

Sometimes this information is summarized in the form of a memory aid by making use of the following statement:

Can Dead Men Vote Twice

Reading from left to right we have C D M V T—Compass, Deviation, Magnetic, Variation, True. Reading the other way, from right to left, we have T V M D C—True, Variation, Magnetic, Deviation, Compass.

However, it is impossible to add or subtract a quantity known as east or west. Therefore, it must be given an algebraic sign (plus or minus). To solve for compass heading when true heading is known, a good rule to remember is: East is least, and west is best. This means easterly errors are subtracted and westerly errors are added. When proceeding from compass heading to true heading, the signs are reversed. Figure 7-11 offers this easy method of application.

DISTANCE

Distance, as previously defined, is measured by the length of a line joining two points. In

112

AC.81

Figure 7-11.—Aplication of compass errors.

navigation the most common unit used for measuring distance is the nautical mile. Since miles have various lengths, one should be careful to specify which mile is meant.

In the U.S. one mile has been defined by statute to be 1,760 yards or 5,280 feet. This is called a statute mile. Navigators use the nautical mile as a distance unit. The DOD has adopted the International nautical mile which equals 6,076.10 feet.

For most practical navigation purposes, all of the following units are used interchangeably as the equivalent of one nautical mile:

1. 1,852 meters (6,076 feet approximately).
2. One minute of arc on the earth's Equator (geographical mile).
3. One minute of arc on a meridian (one minute of latitude).
4. 2,000 yards (for short distances).

Closely related to the concept of distance is speed, which determines the rate of change of position. Speed in air navigation is expressed in nautical miles per hour. When the measure of distance is nautical miles, it is customary to speak of speed in terms of knots. Thus, a speed of 200 knots and a speed of 200 nautical miles per hour are the same thing; however, it is incorrect to say "200 knots per hour" unless referring to acceleration.

TIME

One of your earliest experiences in the Navy was that of learning nautical time. This time is expressed in accordance with the approved naval practice; using the 24-hour day with the hours and minutes expressed in a 4-figure group. In working daily as an Air Controlman, a thorough knowledge of time is necessary, particularly in handling communications, processing flight plans, and checking on overdue aircraft.

As seen from the earth, the sun appears to travel across or orbit the earth. The fact that the sun rises in the east and sets in the west seems to substantiate this. However, the opposite is actually true. The earth orbits the sun and the earth's rotation on its axis creates the illusion that the sun goes around the earth. This is called the "apparent motion of the sun." Since the sun, for all practical purposes, appears to move from east to west, it is a good idea to remember that TIME IS ALWAYS LATER TO THE EAST. (See fig. 7-12.)

AC.82

Figure 7-12.—Noon over a meridian MM'.

10522

Greenwich Mean Time

For uniformity, the meridian of Greenwich, England, has been selected as the prime meridian from which time is measured. You may recall the prime meridian is also the basis for measuring longitude. The moment the sun crosses the meridian, it is noon of that date. Therefore, it can be noon at only one meridian at the same moment. This gives us a common time known as Greenwich Mean Time (GMT) or Greenwich Civil Time (GCT). GMT gives us a reference time to locate time at other points on the earth.

Zone Times and Description

The world is divided into 24 time zones whose central meridians are 0°, 15°, 30°, 45°, etc. All places in any time zone keep the same mean time of the central meridian. Hence, the time can differ only by an integral number of hours from the time at Greenwich.

The local mean time at any one place differs from the mean time at Greenwich by the difference in longitude, 1 hour for each 15°. If local mean time was in common use, there would be a great diversity in the times used at various places. For example, an aircraft flying in an easterly or westerly direction would find that changes in longitude would result in comparable changes in local time.

Late in the 19th century, Congress adopted a uniform system applicable to the continental United States, establishing four time zones. Each central meridian was designated the standard meridian and its local mean time was designated as standard time within its zones. The U.S. time zones are as follows:

ZONE	CENTRAL MERIDIAN
Eastern standard	75° W
Central standard	90° W
Mountain standard	105° W
Pacific standard	120° W

Boundaries of the standard time zones are somewhat irregular, to eliminate inconvenient time changes when traveling. In some cases, cities and states have placed themselves in zones east of the ones in which they would naturally fall.

Generally, in navigation, the standard time zones extend from pole to pole and are exactly 15° wide in longitude. In this system of zone time (ZT) the standard meridian is always the nearest meridian divisible by 15° of longitude. (See fig. 7-13.)

The zone is numbered for the multiple of 15° and labeled plus (+) if in west longitude and minus (-) if in east longitude. Thus, zone +1 extends from pole to pole 7 1/2° on each side of the standard meridian at 15° W, and zone -5 centered on 75° E, extends from 67 1/2° E to 82 1/2° E. The zero zone centered on Greenwich extends from 7 1/2° E to 7 1/2° W, and the twelfth zone centered on the 180th meridian, from 172 1/2° W, to 172 1/2° E; that half in west longitude being designated +12 and the half in east longitude -12. (See fig. 7-13.)

In the zone time system an instant of time is uniquely described by the time and the zone description (ZD) or letter suffix; for example, 1745 zone +5 or 1745 R. The limits, description, and letter suffix of each zone are shown in figure 7-13.

For brevity of communication, the zones are sometimes designated by a letter suffix (mentioned in the preceding paragraph) instead of a zone description. Thus, zones in east longitude are lettered A through M (omitting J), and zones in west longitude are lettered N through Y. The letter Z is reserved for the zero zone, denoting Greenwich time, commonly referred to as ZULU time.

Zone Identification

One of the principal advantages of the zone time system in navigation is the ease with which any instant of time can be converted to GMT, or vice versa. In order to find the number for the ZD, you already know that you will divide any given longitude by 15°. If, when dividing, the remainder exceeds 7°30', add one unit to the answer that you received. For example, let us say that we desire to find the ZD for longitude 142°45'W. Immediately upon observing that it is a westerly longitude, we find the first component of our ZD to be a plus (+). Then we divide the longitude by 15° to find the zone in which we are located:

```
        9
15°/143°45'
    135
     8°45'
```

Since the remainder exceeds 7°30', add one full unit to the quotient (9), resulting in a ZD of +10

10523

AC. 83

Figure 7-13.—Standard time zones.

10524

removed in time from Greenwich. Figure 7-13 shows that longitude 143°45'W has a ZD of +10.

Zone Time, West

In examining figure 7-13, imagine the sun to be over the meridian 15°W. What time is it in the entire band from 7 1/2°W to 22 1/2°W? By referring to the basic rule we know that it is exactly 1200 in the entire time zone when the sun is exactly over the central meridian for that zone. What time is it now on the Greenwich meridian? It is one hour later, or 1300. Thus, GMT was found by adding the ZD, which obviously represents hours, to the ZT. From this calculation the formula

$$GMT = ZT + ZD$$

is derived, and consequently

$$ZT = GMT - ZD.$$

$$GMT = ZT + ZD$$

$$GMT = 1200 + (+1)$$

$$GMT = 1300$$

and

$$ZT = GMT - ZD$$

$$ZT = 1300 - (+1)$$

$$ZT = 1200$$

At this point, if you are unfamiliar with the laws governing adding and subtracting signed (positive and negative) numbers, refer to Basic Mathematics, Volume I, NavPers 10069 (Series).

Zone Time, East

To determine times in east longitude, the same basic procedure and formulas are used. Imagine the sun directly over the meridian 30° east. What time is it at Greenwich? By referring to figure 7-13 or by dividing the longitude by 15, we know that the time zone or ZD is -2, and 30° east is the central meridian for this zone making the ZT 1200. Remembering that time is always later to the east and using the formulas we can determine the GMT.

$$GMT = ZT + ZD$$

$$GMT = 1200 + (-2)$$

$$GMT = 1000$$

(Adding unlike signs indicates subtraction.)

Time Conversions

Greenwich time provides a standard time to which all other times may be referred, and represents a most convenient method of determining times in different zones. For example, assume it is 1500 in a city in zone + 5 (ZT_1), on 1 May, and you want to know the time in a city in zone -3 (ZT_2). Use the formulas as follows:

$$GMT = ZT_1 + ZD_1$$

$$GMT = 1500 + (5)$$

$$GMT = 2000$$

(Adding like signs is simply addition.)

$$ZT_2 = GMT - ZD_2$$

$$ZT_2 = 2000 - (-3)$$

$$ZT_2 = 2300$$

(Subtracting -3 is equivalent to adding +3.)

Frequently time conversion problems involve calculations which result in different dates. To see how this may happen, consider the apparent motion of the sun from 179° east longitude across the face of the chart in figure 7-13 to 179° west longitude. This suggests that exactly at 1200 on the 0° or Greenwich meridian, the date is the same around the world since in ZD - 12, ZT = 2400, and in ZD + 12, ZT = 0000 (ZT = GMT - ZD). This also suggests that each new day begins at the 180° meridian (international date line). Using Greenwich as the reference time to determine ZT in different ZD's, dates should be included in the calculation to maintain the correct day. Consider the following examples:

1. ZT = 0700, 15 June; ZD -5. What is the correct time in ZD + 4? Solution:

$$GMT = ZT + ZD$$

$$GMT = 0700, 15\ June + (-5)$$

GMT = 0200, 15 June

ZT = GMT - ZD

ZT = 0200, 15 June - (+4)

(At this point we cannot subtract 4 hours from 0200, so we must add 24 hours (1 day) to the ZT to permit the mechanical operation of the problem. Since it is always later to the east, the 24 hours we are adding has already elapsed so we must subtract 1 day from the date.)

ZT = 2600, 14 June - (+4)

or

ZT = 2200, 14 June.

2. ZT = 2100, 31 Aug, ZD + 7. What is the correct time in ZD - 5? Solution:

GMT = ZT + ZD

GMT = 2100, 31 Aug + (+7)

GMT = 2800, 31 Aug.

(Considering again that time is later to the east and the answer exceeds 24 hours, this would indicate that GMT = 0400, 1 Sept. However, it is usually more convenient to wait until the problem is complete to subtract the 24 hours.)

ZT = 2800, 31 Aug. - (-5)

ZT = 3300, 31 Aug.

or,

ZT = 0900, 1 Sept.

Chronometers and Time Signals

Time is determined in the various countries of the world by national observatories such as the U.S. Naval Observatory at Washington and the Royal Observatory at Greenwich. A bureau, coordinated by an international agency, sets up uniform computing procedures, compares time signals, etc.

Accurate time is essential in navigation and air traffic control. Chief among the navigational timepieces is the chronometer. It is a clock of unusually fine construction, designed for extreme accuracy and dependability, and built to withstand shock, vibration, and variations of temperature. Even a chronometer cannot keep exact time indefinitely. The chronometer is checked with a radio time signal to determine its accuracy.

On account of their simplicity and accuracy, time signals are transmitted mainly be radio. Naval Observatory time is broadcast in this country by the naval radio station NSS at Annapolis, Md., NPG at Mare Island, Calif., and others. These broadcasts are sent on a continuous wave (CW) so that they can be heard only be receivers suited to code reception. Signals are transmitted during the last 5 minutes of the hour.

Station WWV at Washington, D.C. continuously broadcasts signals based on Naval Observatory time. These broadcasts may be heard with any ordinary radio receiver. Complete schedules and information on Navy time signals can be found in FLIP, Planning, Section III.

ELEMENTARY PLOTTING

From the time an aircraft departs one station until the time it arrives at destination, the pilot or navigator is very busy. In order to get an aircraft to a given destination and back again, the navigator must keep an accurate account of the aircraft's progress on the chart, plus a complete record or log.

Plotting and measuring are the basic operations of navigation. Plotting is the establishment of points or lines on a chart with reference to the meridians and parallels. Measuring means the measurement of direction and distance on a chart. If one is to understand the fundamentals of plotting, he must be familiar with some of the plotting terms, standard symbols and labels, and the use of plotting and measuring tools.

PLOTTING TERMS AND SYMBOLS

Directions and Lines

True course (TC) is the intended direction or path of travel over the surface of the earth expressed as an angular distance from true north. The course line on a chart represents the intended path or direction of travel. A course line is comprised of the course and the element of distance. Track (TR) is the actual path followed by the aircraft over the ground.

10526

Speeds

Groundspeed (GS) is the speed of the aircraft over the ground, most commonly expressed in knots. True airspeed (TAS) is the rate of motion of the aircraft relative to the surrounding air.

Position

Dead reckoning position (DR) is determined by advancing a known position on a specified course for a specified distance. It is established by keeping accurate account of time, speed, and direction traveled since the last known position. A fix is an accurate position determined without reference to any former position. A way point is a reference point between the point of departure and destination.

Time

Time of departure (TD) is the time at which the aircraft leaves the point of departure. Minutes or minutes on leg (min) is the interval of time, estimated or actual, required for the aircraft to fly a given distance at a given groundspeed. Estimated time of arrival (ETA) is the predicted time of reaching a destination or way point. It is determined by estimating the length of time required for the flight from the point of departure to the destination or way point and adding this to the time of departure. Since the groundspeed is constantly affected by various factors in flight, the ETA is revised at frequent intervals if needed during the flight. Actual time of arrival (ATA) is the time at which the aircraft actually arrives at its destination or way point.

Distance

Miles on course (MC) is the distance, predicted or actual, which the aircraft travels on any given course. It may be one leg of a search pattern, or it may be the entire distance from the point of departure to the destination.

Application of Plotting Symbols

True course (TC) is indicated by a solid line with a single arrowhead showing direction. (See fig. 7-14.) Track (TR) is indicated by a solid line with double arrowheads showing direction. It is sometimes shown darker than a course line to increase the contrast between the two. A fix is

AC.84

Figure 7-14.—Typical chart work illustrating correct symbols and labels.

indicated by a triangle, labeled with the time and title, FIX. A dead reckoning position is indicated by a circle, labeled with the time and title, DR. The point of departure and destination are graphically illustrated as squares. They may be considered fixes; but in order to distinguish them from the fixes obtained while in flight, the triangle is not used.

PLOTTING EQUIPMENT

The pencil and eraser are the most elementary and indispensable articles of plotting equipment. The pencil should be of soft lead and well sharpened. A hard lead pencil is undesirable, not only because it makes the lines which are light and difficult to see, but also because it makes lines which are difficult to erase. A soft eraser, which will not smudge or damage the chart is used.

A pair of dividers is an instrument used for measuring distance on a chart in the following manner. Separate the points of the dividers to the desired distance on the proper scale (usually the latitude scale), and transfer this distance to the working area of the chart. In this way, lines of desired length can be marked off.

While measurement is being made, the chart should be flat and smooth between the points of

10527

dividers, because a wrinkle may cause an error of several miles. Points on a chart may be marked by applying slight pressure on the dividers so that they prick the chart. Too much pressure results in large holes in the chart and tends to spread the points of the dividers farther apart, reducing measurement accuracy.

A plotter is an instrument designed primarily to aid in drawing and measuring lines in desired directions. Plotters vary from complicated drafting sets to a simple plotter combining a type of protractor and straightedge. Figure 7-15 (A) and (B) shows two widely used aircraft navigational plotters.

The rectangular model plotter, type B-2(A), is standard equipment, and is replacing the older AN model (B), which is still in use. The B-2 is made of very heavy plastic to resist breakage when cold, and has the advantage that two or more plotters can be joined to facilitate

AC.85

Figure 7-15.—Navigational plotters. (A) Type B-2; (B) type AN.

plotting long lines. Both plotters carry convenient scales for measuring distance in nautical miles on a chart.

Plotting Sheets

A plotting sheet is a blank or incomplete chart. It has latitude and longitude lines, and it may have a compass rose for measuring direction, but little or no additional information. The meridians are usually unlabeled so the plotting sheet can be used for any longitude. Any projection may be used for constructing plotting sheets; however, only the Mercator is referred to here since it is the most commonly used. NOTE: Both chart construction (projection) and the Mercator projection are discussed later in this chapter.

Much of the plotting work of an air navigator is done on universal plotting sheets (Mercator projection) carrying only parallels of latitude or meridians or both. Regardless of the sheet selected, some preliminary preparation is usually necessary. The points of departure and destination, and important navigational aids such as radio stations, prominent landmarks, etc., should be plotted. A plotting sheet should be oriented correctly, depending upon latitude. If the plotting sheet is to be used in south latitude, the sheet is turned upside down so that the latitude increases toward the south. On most plotting sheets only the parallels bear printed numbers, and the meridians should be assigned the appropriate values for the longitude of the flight involved. West longitude increases toward the western (left) edge, and east longitude increases toward the eastern (right) edge. This is true both in north and south latitude. Common mistakes encountered in numbering meridians are giving two meridians the same number and, in some cases, omitting a number.

PLOTTING POSITIONS

One method by which positions can be plotted is illustrated in figure 7-16. This illustration shows how to locate a position at 30°21'N, 87°17'W (Pensacola, Fla.). To locate this position, place the straightedge of the plotter in a vertical position at 87°17' W on the longitude scale. Set the dividers for 21 minutes of latitude from the latitude scale. Hold one point of the dividers on latitude 30° N, and against the straightedge. Let the other point also rest against the streightedge upward, and with a little pressure lightly prick the chart. This marks the desired position.

PLOTTING AND MEASURING COURSES

After the departure point and destination have been plotted on the chart, the next step is to plot the course line between these two points with a plotter or several plotters connected. After the course line has been plotted and labeled as was shown in figure 7-14, measure its direction. Anywhere along the line to be measured, place the points of the dividers or a pencil. Let the plotter slide on this point, and swing the plotter until (1) the straightedge is parallel with the line to be measured, and (2) the center hole is over any meridian. The direction is indicated on the protractor at the meridian. Keep in mind the approximate direction of the line when reading the protractor. A course line has two possible directions—the correct one and the reciprocal. Errors made by plotting or measuring reciprocals are common. By retaining a mental picture of the compass rose while plotting, the incorrect measurement of reciprocal courses and bearings is avoided.

MEASURING DISTANCE

One of the disadvantages of the Mercator projection is its lack of a constant scale. If the two points between which the distance is to be measured are approximately in a north-south direction, and the total distance between them can be spanned, the distance can be measured on the latitude scale opposite the midpoint. However, the total distance between any two points that do not lie approximately north or south of each other should not be spanned unless the distance is short. All distances should be measured as near the midlatitude as possible. If a long east-west distance is spanned, the number of miles indicated by the latitude scale is incorrect. This is because the scale expands on the higher latitude side of the midlatitude faster than it contracts on the lower latitude side.

In the measurement of the long east-west distances, a midlatitude lying approximately halfway between the latitudes of the two points should be selected. By using dividers set to a convenient, reasonably short distance (60 nautical miles, picked off at the midlatitude scale), one may determine an approximate distance by walking off units along the line to be measured

10529 10528

Figure 14-16. —Phantastron delay system.

the PPI when the scope is in a nondelayed condition. This delay marker indicates the point at which the delayed or expanded sweep will start. (EXAMPLE: When 60 miles of sweep delay is desired, the delay marker is adjusted to aline with the 60-mile range marker. When the delay is switched-in, the sweep starts at the center of the scope after 60 miles of delay. Thus if a 30-mile sweep is used, the scope will cover 60 to 90 miles.)

DELAY LINE SYSTEM

Delay lines may be used for accurate short periods of delay such as delaying the start of a PPI sweep. This enables the sweep and transmitter to be triggered at the same time. They are also used to generate coded pulses. Special types of pulse equipment, in which pulses are transmitted at one location and received at another, frequently use coded pulses. These pulses are used for the purpose of preventing signals of the same carrier frequency, that contain similar pulses, from interfering with the desired signal pulses. A common type of coding is that in which a group of pulses is used for each actual pulse. The pulses in each group are separated by accurate and unequal time intervals. The means most frequently used for generating the pulses is a circuit that contains the delay line (artificial transmission line).

A simplified circuit for producing a rectangular pulse by the use of an artificial transmission line is shown in figure 14-17. The characteristic impedance of the transmission line is 2,500 ohms. The resistor, R2, across which the output pulse is to be developed is equal to this characteristic impedance. Resistor R1, through which the line is charged, is made much larger than the characteristic impedance so that it is an apparent open circuit during the discharge of the line. The capacitors are all charged to 600 volts if switch S is left open for a sufficient time. If the switch is closed after the line has been charged, a current immediately starts to flow through R2. The line may be considered as a battery with an

1050

AC.86

Figure 7-16.—Plotting a position.

as shown in figure 7-17. The number of steps walked off should be multiplied by the length of each step, and the length of any last step added.

The scale at the midlatitude is accurate enough if the course line does not cover more than about 5° of latitude. If the course line does exceed this amount, or if it crosses the Equator, it should be divided into two or more legs and the length of each leg measured with the scale of its own midlatitude.

PLOTTING LINES OF POSITION (LOP'S)

Suppose, for example, the aircraft is flying over a railroad, but its location along the length of the railroad is not known. If the railroad can be located on the chart, a line of position is established, but not a fix. Then, another railroad that crosses the first is seen. When the second railroad is located on the chart, the exact

10530

AC.87

Figure 7-17.—Measuring a distance in steps.

location of the aircraft along the first railroad is known. Thus, a fix is established. Remember, a fix is an accurate position. Therefore, a fix is determined when the aircraft is over two intersecting LOP's simultaneously.

With chart reading, a fix can often be obtained by finding a specific landmark. However, with other navigation aids, fixes are not obtained directly. Rather, with the exception of radar and TACAN, each fix is established by two or more LOP's which are independently obtained.

It has been seen that a LOP may be a visible line on the ground like a railroad track or another object of known position. However, a LOP is not usually visible until it is drawn on a chart. A radio LOP is obtained by finding the direction of a radio station from the aircraft by means of a radio compass. Having obtained this radio LOP, it is plotted on the chart. Once plotted, it is no different from one obtained by visual reference or by any other aid. LOP's of different types and origins may be crossed to obtain a fix.

LOP's Established by Bearings

A bearing may be measured with reference to true north or with reference to the longitudinal axis of the aircraft; in either case, it is an angle between 0° and 360°.

There is a simple relationship between true heading (TH) of the aircraft, true bearings (TB) of an object, and relative bearing (RB) of an object. True heading is the angle measured from true north clockwise to the longitudinal (fore and aft) axis of the aircraft. Relative bearing is the angle measured from the longitudinal axis of the aircraft, clockwise to a line passing through an object. The sum of these two angles is the angle measured from true north clockwise to the line passing through the object. Therefore, this angle is the true bearing of the object expressed in the following equation:

$$TH + RB = TB$$

Thus, to obtain the true bearing (TB), measure its relative bearing (RB) and add it to the true heading (TH) of the aircraft.

As illustrated in figure 7-18, an aircraft is flying a TH of 210° and a relative bearing of 070° is obtained from a mountain peak. What is the true bearing of the peak? Add TH (210°) to RB (070°) to obtain TH (280°).

By changing the basic formula, you may obtain any one of three components if the other two are known. Thus, to find the true heading, change the formula to read TB - RB = TH. To find relative bearing, change the formula to read TB - TH = RB. Whenever an angle exceeds 360°, it is necessary to subtract 360° to determine the correct bearing.

AC.88

Figure 7-18.—TH + RB = TB.

Plotting from Known Positions

In plotting LOP's, it is obvious that a plot cannot be made from the aircraft's position as it is unknown. Plot the LOP from the origin, which is a known position. To plot the LOP, use the reciprocal of the true bearing of the object from the aircraft.

When using the plotter to draw a LOP, you need not compute the reciprocal mathematically. Simply aline the plotter so that the point of origin lies on the straightedge and the center hole and true bearing (as read on the scale) are over the same meridian. Then draw the LOP toward your position.

Although two intersecting LOP's determine a fix, three intersecting LOP's give a more accurate fix. It is possible to combine a radio LOP with a radar LOP, or a loran LOP with a visual LOP, etc. If three LOP's intersect at one point, use that point for the fix. Usually, however, the errors in obtaining the LOP's and in plotting them will cause the LOP's to form a small triangle for the fix. When this happens, use the center of the triangle.

Positioning by RADAR and TACAN

Airborne radar is oriented so that 360° is represented by the nose of the aircraft. By use of a radar scope in the aircraft, the relative bearing, and also the distance the aircraft is from known landmarks can be determined, providing a fix. (See fig. 7-19.)

AC.89

Figure 7-19.—Positioning by RADAR and TACAN.

TACAN provides bearing and distance information. By use of aircraft instruments, the pilot can determine what TACAN radial his aircraft is on and its distance from the TACAN station. Since the position of the TACAN station is known, a fix, or the aircraft's position, can be determined relative to the TACAN station. (See fig. 7-19.)

WIND AND ITS EFFECTS ON NAVIGATION

If air masses were absolutely still, relative to the ground, navigation of aircraft would be very simple. A pilot could easily fly any desired course by merely correcting for variation and deviation. He could calculate ETA's and determine positions en route by using true airspeed.

Unfortunately, however, this situation never exists. The air masses are always moving. This produces the phenomenon called wind. Wind is air in approximate horizontal motion and has both direction and speed.

Wind direction is expressed in the direction FROM which the wind is blowing. Keep in mind that wind direction differs from other directions used in navigation in that it is the direction from which, rather that the direction toward which, motion occurs. True heading, for example, is the direction toward which an aircraft is headed.

Windspeed is the rate of movement or speed of the air over the earth's surface. To maintain conformity, both Aerographer's Mates and Air Controlmen express windspeed in knots. The term wind velocity (WV) includes both wind direction and speed. In diagrams involving wind, which will be discussed in detail in this section, the wind vector is labeled, for example, WV 180°/25K, and is indicated by a solid line with three arrowheads.

DRIFT AND DRIFT CORRECTIONS

Any vehicle traveling on the ground, such as an automobile, moves in the direction in which it is steered and is affected very little by the wind. An aircraft, however, seldom travels in exactly the direction in which it is headed. This is understood when the effect of wind on the flightpath is considered.

Consider first the effect of wind on a balloon which has no motion of its own. A balloonist never feels any wind because he is

10532

suspended in the body of air and moves with it. Consequently, no air moves past him. A balloon in the air is just like an empty bottle floating down a river; the bottle travels with the current.

Any free object in the air moves downwind with the speed of the wind. This is just as true of an aircraft as it is of a balloon. If an aircraft is flying down wind in a 20K wind, the body of air in which it is flying moves 20 nautical miles in one hour. Therefore, the aircraft also moves 20 nautical miles downwind in 1 hour. This movement is in addition to the forward movement of the aircraft through the body of air.

The path of an aircraft over the earth is determined by two unrelated factors: (1) the motion of the aircraft through the air mass, and (2) the motion of the air mass across the earth's surface. An aircraft's movement over the ground is comparable to a boat crossing a river. If there is no current in the river, a boat starting at one shore of the river and rowed perpendicular to the river's edge would end at a point on the opposite shore directly across from its starting point. However, if there is a current, the boat will be carried downstream. Until the boat eventually reaches the opposite shore, the displacement downstream is dependent upon the velocity of the river current and the speed of the boat.

The aircraft shown in figure 7-20 (A) departs from point X on a heading of 360° and flies for 1 hour in a wind of 270°/20K. The aircraft is headed toward point M, directly North of X, so its true heading (TH) is represented by the line XM. If there is no wind, the aircraft would be at point M at the end of the hour. However, there is a wind. The body of air in which the aircraft is flying moves 20 nautical miles toward the East during the hour, and the aircraft moves with it. Consequently, at the end of the hour the aircraft is at point N, 20 nautical miles downwind from point M. Thus, line XM is the intended path of the aircraft, line XN is the actual path of the aircraft over the earth.

AC.90

Figure 7-20.—(A) Drift angle; (B) drift correction angle.

10533 10238

The effect, then, of this wind on the aircraft causes it to follow a different path over the ground than was originally intended.

The angular difference between TH and TR (TRACK) is the drift angle, commonly called drift. As shown in figure 7-20(A), the aircraft has drifted to the right. This is known as right drift. Drift is always labeled right or left.

Thus far it has been learned that wind causes drift and affects the track of an aircraft. But we have not determined how to adjust the true heading to allow for drift, and thus maintain a desired true course and track. The true course (TC) and track (TR) must always coincide to arrive at a given point by the most direct route.

Figure 7-20 (B) shows the drift correction angle needed to proceed from point X to M, a true course of 360°, wind 270°/20K. As described above, if the pilot flies a true heading of 360° he will not arrive at point M but at some point downwind from point M as shown in figure 7-20 (A). Therefore, he must head for some point upwind from M and let the wind (right drift) bring him to point M. If the aircraft flies for 1 hour it will drift 20 nautical miles downwind, therefore, the pilot must head for a point 20 nautical miles upwind from point M. Flying the heading XB, he arrives at point M. The track of the aircraft is XM.

Heading an aircraft upwind in order to maintain the true course and intended track is called correcting for drift. The angle MXB is the drift correction angle, or simply drift correction. Drift correction is the correction which must be applied to a true course to find the true heading needed to make good that true course. The angle MXB is the correction to the left which must be made for a right drift condition in order to make TR and TC coincide.

A change of heading will also affect the distance traveled over the ground in a given time. This rate of travel, relative to the earth's surface, is known as groundspeed (GS). Therefore, with a given wind, the GS varies on different headings.

THE WIND TRIANGLE

In aerial navigation there are many problems to solve involving speeds and directions. Primary concern is with track, groundspeed, true heading, true airspeed, wind direction, and windspeed. Often, four of these quantities will be known and it will be necessary to determine the other two. For example, the true heading, true airspeed, wind direction, and windspeed will be known; track and groundspeed unknown. In order to solve such problems, it is necessary to understand the relationships of the six quantities.

These quantities are represented by vectors. Any quantity having both direction and any other magnitude such as speed or distance is called a vector quantity, and can be represented by a line called a vector.

Two or more vectors can be added together simply by placing the tail of each succeeding vector at the head of the previous vector. These vectors when added together are known as component vectors. The sum of these component vectors can be determined by connecting, with a straight line, the tail of one vector to the head of the other. This sum is known as the resultant vector. By its construction, the resultant vector forms a closed figure or triangle.

The solution of a problem involving velocities and drift is usually done by means of a vector diagram called a wind triangle. Naval aviators use a standardized system of symbols. The wind vector is represented by a line EW as shown in figure 7-21. Note that EW is drawn to show in the direction FROM which the wind is blowing. The true heading-true airspeed vector is the line WP. The track-groundspeed vector is the line EP. These symbols are always used to represent the same quantities.

AC.91

Figure 7-21.—Determining TR and GS.

We will first work a wind triangle that gives us the track and groundspeed. Given are TH 334°, TAS 90K, WV 270°/40K. Inasmuch as wind exists on every flight, we will draw the wind vector first. This is done by placing the plotter along any meridian and alining the straightedge of the plotter to indicate 270°. Use the scale on the straightedge of the plotter to determine the length of the vector (40 units). Label this vector EW. We are now ready to draw the true heading-true airspeed vector which is WP. Aline the plotter, from W, along the true heading, which is 334°, and measure the length of the vector to 90 knots. This, too, is measured on the straightedge of the plotter scale. At the end of the vector, label point P. To find the track and groundspeed, aline the plotter along the vector EP. Draw a line to join E and P. Line EP is the track (000°), and its length (81 units) is the groundspeed. (See figure 7-21.)

Another, and the most common type of vector problem used, is the one in which a pilot measures the direction of the true course from a chart, and gets a forecast of wind from weather service. Also, he knows the true airspeed at which he will fly his aircraft.

To find the true heading and groundspeed, the following procedure is used. First, plot the wind. Aline the plotter so the straightedge is parallel to the direction of the wind. Again measure the wind velocity on the scale (WV 215/15) at the bottom of the plotter. Now, aline the plotter along the true course (295°), and from point E draw a line of indefinite length. This line will show the true course or track necessary to travel. But, since it was measured from point E, the length of the vector, which is actually the groundspeed, cannot be determined. However, the true airspeed given is 125 knots. Next, aline the plotter from point W, so that the scale of the plotter falls across the line drawn from point E, and the length of the WP vector represents the true airspeed of 125 units on the scale. Now, measure the direction of the WP vector, read the true heading, measure the length of the EP vector, and read the groundspeed. (See fig. 7-22.) The true heading is found to be 289° and the groundspeed 122 knots.

Still another type of problem used is that of finding the true heading and true airspeed when the track and groundspeed are known. Given are TR 315°, GS 110K, WV 045°/30K. Again, on this type of vector, plot the wind first. The wind is drawn in the same manner as before. (See fig. 7-23.) Now aline the plotter along the track, and from point E measure the length of the vector EP to 110 knots. This is the groundspeed. At this point label point P. Aline the plotter along the WP vector and read the direction or the true heading, and measure the length of the WP vector to find the true airspeed. By careful plotting, we find the heading to be 331° and the required airspeed to be 114 knots.

It has been shown that if any four of the six basic elements are known, the remaining ones can be found by drawing a wind triangle and measuring these parts. Care should be used to place the arrowheads on the lines of the triangle, otherwise the reciprocal direction may be used by mistake. The directions of the elements of the wind triangle are always E to W, W to P, and E to P, as shown in the three preceding illustrations.

10535

AERONAUTICAL CHARTS

From ancient times, man has attempted to reproduce accurately the surface of a sphere on a plane surface. The procedure is similar to that of taking a hollow rubber ball and flattening it; the ball will stretch and split before it will flatten. This is exactly the problem which is encountered in chart construction. As in the case of the rubber ball, when the earth is displayed on a plane surface, some features are distorted and others are lost altogether. Much of the distortion is minimized with the introduction of various mathematical modifications of the geometric map, and the most desirable navigational properties can either be accurately or very nearly accurately portrayed.

FACTORS IN CHART CONSTRUCTION

The surface of a sphere or spheroid is said to be undevelopable because no part of it may be spread out flat without distortion. A plane, cylinder, or cone, which can be easily flattened, is called a developable surface. The method of representing all or part of the surface of a sphere or spheroid on a plane surface is called a chart projection.

Geometric projections are actual projections of graticule (lines of latitude and longitude) of the reduced earth onto a developable surface. In theory, a chart could be constructed by placing a light source in a hollow plastic model of the earth with the parallels and meridians inscribed on it, and projecting this graticule on some developable surface. This surface, if it is not a plane, is unrolled to form a flat surface. Any chart that can be constructed in this manner is called a geometric or graphic projection. The appearance and properties of the resultant chart will depend upon two factors: The type of developable surface and the position of the light source within the plastic model of the earth. In actual practice, the projection is constructed mathematically.

Mathematical projections are constructed to provide certain properties which cannot, in theory, be constructed geometrically.

There are many projection methods available for use in chart construction. Each projection has distinctive features which make it preferable for certain uses. No one projection is best for all conditions. Some of the desirable features are:

1. Conformality. Conformality provides that the angle between intersecting curves on the earth will be preserved on the chart. For a chart to be conformal, parallels and meridians must intersect at right angles. In addition, scale or scale expansion must be the same along the meridian as it is along the parallel. Scale on a conformal chart will vary from point to point, but provided that the variation is the same in all directions, the requirement is met.

2. Constant and correct scale. An ideal model of the earth would have constant and correct scale; i.e., the distance of every place from every other place would bear a constant ratio to the true distance on the earth. Unfortunately, the earth's surface cannot be developed into a plane without stretching or shrinking, which prevents correct and constant scale representation over the entire projection.

3. Correct shape representation. To possess the property of correct shape, a chart must be conformal and the scale must be constant and correct in all directions. As pointed out previously, this latter prerequisite is not possible to obtain over the entire projection.

4. Straight line. The nature of a straight line on a chart is equally as important as conformality. The rhumb line (a line between any two points which crosses all meridians of the earth at the same oblique angle) and the great circle (defined previously in this chapter) are the two curves that a navigator might wish to have represented on a chart as a straight line. The rhumb line is desirable because it is convenient to fly, and the great circle is flown because it provides the shortest path between any two points.

5. Coordinates easy to locate. The geographic latitudes and longitudes of places should be easily found from their positions on the chart; and conversely, positions should be easily plotted on the chart when the latitudes and longitudes are known.

Figure 7-24 shows types of projections and basic characteristics of the projections from which the majority of aeronautical charts used by AC's are constructed.

INFORMATION SHOWN ON AERONAUTICAL CHARTS

An aeronautical chart is a pictorial representation of the earth and its culture. It can provide a picture of any region of the earth.

Figure 7-24.—Chart projections. AC.94

Several miscellaneous terms frequently utilized in reference to aeronautical charts are defined as follows:

1. Small scale chart. A chart portraying large areas, as the world, a hemisphere, continent, or a country. Usually this is referenced to scales of 1:2,000,000, 1:5,000,000, etc.

2. Large scale chart. A chart portraying small areas with a relatively large amount of detail, as an area of less than state or county size. Usually this refers to scales of larger than 1:1,000,000, such as 1:500,000; 1:200,000; or 1:100,000.

3. Graticule. This is the portrayal of meridians of longitude and parallels of latitudes.

4. Base detail. This includes all features portrayed on a chart other than those on the aeronautical or grid overprint. It includes relief, culture, hydrography and vegetation.

5. Contours. A contour is represented by a line on a chart connecting all points of a given elevation above sea level. The shoreline of an ocean may be considered as the mean 0-foot contour. On a steep slope contours are close together; on a gentle slope they are farther apart.

6. Gradient tints. This means different colors used to depict intervals between certain contour lines.

7. Spot elevations. A dot with an elevation value depicts an accurately measured elevation above sea level at a specific location. On some charts a small "x" is used to indicate an approximate elevation at a specific location. If the exact location of an elevation is unknown, only the figures are shown.

8. Water tint. This depicts open water areas such as oceans and lakes by a solid tint, usually a light blue.

9. Water vignette. This is an alternate treatment of open water wherein the water is depicted with a deep or dark tone along the shoreline, and rapidly but evenly lightened in tone with progression outward from the shore to a blank or white portrayal. This technique makes a chart with large white open water areas easier to plot on, and accentuates small bodies of water and small islands.

10. Land tint. Land tint is a solid tint over all land area with no gradient tints and often no contours.

11. Relief. This refers to physical features related to the relative differences in elevation of the land surface. It includes features such as mountains, hills, plateaus, plains, depressions, etc. Complexity of relief features is dependent upon scale and/or contour interval used. Generally large scale charts show many relief features, whereas very small scale charts can only show major mountain masses.

12. Culture. Culture includes populated places, roads, railroads, installations, miscellaneous construction, such as dams, bridges, and mines. Standard symbology is used. Density of portrayal is related to chart scale, chart use, and the geographic area covered.

13. Hydrography. Hydrography includes coast lines, oceans, lakes, rivers and streams, canals, swamps, reefs, etc. Density is indicated by reference to principal or detailed drainage. Open water may be portrayed by water tint or vignette, or may be left blank.

14. Vegetation. This is not shown on most small scale charts. Forests and wooded areas in certain parts of the world are shown on some medium scale charts. Some large scale charts have park areas, orchards, hedgerows, and vineyards.

15. Aeronautical information includes airfields; electronic communications and navigational facilities such as radio beacons, VOR's, D. F. stations, and broadcast stations; ADIZ's, compulsory corridors, restricted airspace, and warning notes; lines of magnetic variation; and navigation grids.

The amount of detail, extent of features portrayed, and the density of information shown on a chart are governed by the designed purpose of the chart, and the altitude, range, and aircraft performance category for which the chart was designed. In other words, an attempt has been made to portray only that information which will be appropriate to and significant for the altitudes and speed ranges utilized in accomplishing the types of missions for which the chart was designed.

CHART SOURCE, CORRECTIONS, AND PROCUREMENT

The DOD Catalog of Aeronautical Charts and Flight Information Publications lists the current edition of charts which are issued by the Oceanographic Office regardless of source. Included are charts published by the U.S. Naval Oceanographic Office, USAF Aeronautical Chart and Information Center, and the U. S. Coast and Geodetic Survey. Whenever new or revised charts are needed by members of the naval service, all requests should be submitted on Form DD 1149 to the nearest Air Navigation Office or the supporting Oceanographic Distribution Office via the commanding officer.

Charts available at Flight Clearance are kept current by the following publications:

1. DOD Aeronautical Chart Updating Manual (CHUM), which contains:

a. A cumulative listing of significant additions or corrections to be considered when using current editions of USAF/USN published aeronautical charts.

b. Notices of special interest to aeronautical chart users.

10538

NOTE: The CHUM should be made available to flight crews for use during preflight planning.

2. DOD Aeronautical Chart Bulletin, published monthly, which contains availability of new charts and publications; new editions of previously published charts; discontinued charts; and notices of special use to requisitioners.

Place this bulletin in the front of the DOD Catalog.

3. DOD Aeronautical Chart Bulletin Digest published semiannually which contains listings of current editions of charts on issue.

Naval activities are also provided with Memorandum to Aviators and NOTAM's which may include corrections to charts.

NAVIGATION COMPUTERS

The Air Controlman should have a working knowledge of navigation computers as a quick and accurate method of solving simple navigation problems. This knowledge may be used in preflight planning or in-flight assistance to pilots. For example, the pilot of an aircraft observed on radar desires a groundspeed check. Two factors of the problem can be determined immediately from the radar. This information is then applied to a navigation computer, after which an accurate groundspeed is relayed to the pilot.

Various computers have been devised but only the E6D (AN-5834-1B, also called the E-10) is discussed in this training manual.

The E6D computer is really a combination of two devices. One side is a specially designed scale for the solution of wind problems. This side is known as the wind face which is not discussed here, in that its use is for solving problems not normally encountered by the Air Controlman. The other side, known as the slide rule face, is a circular slide rule for the solution of mathematical problems.

The slide rule consists of two circular scales—one a stationary scale, called the MILES SCALE; the other a rotating scale, called the MINUTES SCALE. Each scale has a reference mark, the 10, called the INDEX. The rotation scale also has a black arrowhead at the 60-minute or 1-hour point. This is known as the SPEED INDEX. (See fig. 7-25.)

Graduation of both scales are identical. The graduations are numbered 10 to 100; the unit intervals decrease in size as the numbers increase in size. The first element of skill in using the computer is a knowledge of how to read the scales. For example, there are no numbers between 25 and 30; but it is obvious the larger intermediate divisions are 26, 27, 28, and 29. Between 25 and (unnumbered) 26 there are five smaller divisions; therefore, each of these is 0.2 (1/5 x 1.0 = 0.2) of the larger unit. For a number such as 258, first find 25 (for the 250). Then, since the divisions

AC.95

10238

internal impedance of 2,500 ohms during the discharge time (fig. 14-17 (B)). The voltage across R2 is one-half the voltage to which the line was charged, or 300 volts, since one-half the available voltage is lost across the 2,500-ohm internal impedance, Z_0. If the network consisted only of capacitors, the discharge would follow an exponential curve, and the voltage across R2 would not be constant. However, the inductance and capacitance of the line are so designated that the discharge rate is practically constant.

The discharge of the artificial line can be explained best as follows: At the instant that the switch (fig. 14-17 (A)) is closed, the voltage at point A falls to 300 volts. This can be looked upon as a traveling wave of -300 volts applied at point A to reduce the voltage there immediately from 600 to 300 volts. As the wave moves from A to B the voltage across the line is reduced from 600 to 300 volts. On reaching point B, the wave sees an open circuit, since resistor R1 is very large. The wave is reflected without change in sign, and immediately reduces the voltage at point B from 300 volts to zero as the wave travels back to point A; and the remaining 300 volts across the line is canceled out. On reaching point A, the wave has reduced the voltage across all sections to zero, the wave itself disappearing because it is absorbed by a load which matches the characteristic impedance of the line. The pulse formed across R2 by the line discharge lasts for the time required for the traveling wave to move from the switch end of the line to the open end and back.

A typical line may be constructed by winding may turns of copper wire on a flexible tube of insulating material. This coil is first covered with a thin layer of insulation, and then a braided shield and another layer of insulation. The capacitance between the coil and the shield simulates the distributed capacitance of the actual transmission line and the inductance of the coil simulates the distributed inductance.

MARKER SYSTEMS

Marker systems are used to enable the radar operator to determine the location of targets with great accuracy. This may be accomplished by causing visual guides to appear on the face

Figure 14-17. —Artificial transmission line. (A) Simple circuit for producing a pulse: (B) equivalent circuit during discharge.

1051

here are 2 units each, find the fourth intermediate division (4 x 0.2 = .8) for 258. The slide rule does not indicate where to place the decimal point. You must place it according to commonsense. The 25 on the scale may stand for .25, 2.5, 25, 250, and so on, depending on the figures with which you have to work. The position of the decimal point will not matter in picking the point on the scale which represents the number.

PROBLEMS ON THE SLIDE RULE FACE

The slide rule face of the computer is so constructed that any relationship between two numbers, one on the stationary scale and one on the movable scale, will hold true for all other numbers on the two scales. A slide rule is a mechanical device which solves proportions. A proportion is a statement that two fractions or ratios are equal. Thus, 1/2 = 3/6 is a simple proportion. If you know three of the four numbers or terms of a proportion, you can solve for the fourth. Thus if 2/3 = X/9, it is obvious that X = 6. If you consider the figures on the outer (miles) scale and inner (minutes) scale as the upper and lower parts of a simple proportion, you can set the known values on the computer, and the unknown values will automatically be given by the computer scale. Consider the following examples:

(1) To find distance:

Given—Groundspeed, 204 knots.

Problem—Find the distance traveled in 75 minutes.

Solution (fig. 7-26)—Set the speed index on the minutes scale opposite 204 on the miles scale. Opposite 75 on the minutes scale, read 255 nautical miles on the miles scale.

NOTE: Notice the speed index is part of the proportion when a constant rate per hour is involved such as nautical miles per hour (knots).

(2) To find groundspeed:

Given—Distance traveled, 140 nautical miles; elapsed time, 40 minutes.

Problem—Find groupspeed.

Solution (fig. 7-27)—Set 40 on the minutes scale opposite 140 on the miles scale. Opposite the speed index, read the groundspeed 210 knots.

(3) To find time:

Given—Groundspeed, 160 knots. Destination is 200 nautical miles.

AC.96

Figure 7-26.—Given speed and time to find distance.

AC.97

Figure 7-27.—Given distance and time to find speed.

Problem—Find the time for the aircraft to reach destination.

Solution (fig. 7-28)—Set speed index opposite 160 on the miles scale. Opposite 200 on the miles scale, read 75 on the minutes scale.

(4) To find fuel consumption:

Given—At cruising speed the fuel consumption is 460 pounds per hour. The aircraft has been at cruising speed for 3 hours (180 minutes).

Problem—Find the amount of fuel consumed.

Solution (fig. 7-29)—Set the speed index on the minutes scale to 46 on the miles scale. Opposite 180 (3 hours) on the minutes scale read, 1,380 pounds on the miles scale.

10540

AC.98

Figure 7-28.—Given speed and distance to find time.

AC.99

Figure 7-29.—Given fuel consumption rate and time to find fuel consumption.

(5) To find possible cruising time:

Given—An aircraft uses 35.5 gallons of fuel per hour. The tank holds 100 gallons.

Problem—Find the possible cruising time.

Solution (fig. 7-30)—Set the speed index opposite 35.5 on the miles scale. Opposite 100 on the miles scale, read 169 minutes (2 hours 49 minutes) on the minutes scale.

All mileage and speed in aviation are nautical. Should you be faced with a problem involving statute miles or miles per hour, there is a conversion marker for each of these units on the miles scale. To convert from one unit to another, place the known unit on the minutes scale under the respective unit arrow on the miles scale. Read the equivalent distance or speed under the desired unit arrow. For example, change 120 statute miles to nautical miles. (See fig. 7-31.) Set 120 on the minutes scale opposite the STAT arrow on the miles scale. Read 104 on the minutes scale opposite the NAUT arrow on the miles scale.

AC.100

Figure 7-30.—Given fuel consumption and tank capacity to find cruising time.

Simple multiplication or division can also be done with the E6D. In doing this, use the "10" index instead of the speed index for part of the proportion.

AC.101

Figure 7-31.—Converting statute miles to nautical miles.

In multiplying, set the "10" index on the minutes scale opposite either of the numbers to be multiplied on the miles scale. Then read the answer on the miles scale opposite the other number to be multiplied on the minutes scale. For example, multiply 2 times 12 on the E6D. (See fig. 7-32.) Set the "10" index on the minutes scale opposite 12 on the miles scale. Read the answer (24) on the miles scale opposite the other number to be multiplied (2) on the minutes scale.

When dividing on the E6D, it appears exactly the same as it does when given a fraction. Place the dividend on the miles scale opposite the divisor on the minutes scale. Read the quotient or answer on the miles scale opposite the "10" index on the minutes scale. For example, divide 24 by 8 on the E6D. (See fig. 7-33.) Set 24 (divident) on the miles scale opposite 8 (divisor) on the minutes scale. Read the answer (3) on the miles scale opposite the "10" index on the minutes scale.

In addition to the miles and minutes scales, the slide rule face of the E6D has several other scales. One is marked "For Air Speed Computations" and is used for applying air temperature and pressure altitude to correct the airspeed indicator reading. Another is marked "For Altitude Computations" and is used for applying air temperature and pressure altitude to correct the altimeter reading. Additionally, there are scales to compute for density altitude, to determine true airspeed from Mach number, and to solve for wind correction factors in constant heading flight technique.

10542

CHAPTER 8

AIDS TO AIR NAVIGATION

To understand how communication by radio propagation is possible, a brief consideration of the electrical nature of all matter is helpful.

All matter consists of a great number of tiny units called molecules. Each molecule consists of one or more atoms. An atom is composed principally of subatomic particles called electrons, protons, and neutrons. Protons and neutrons are a closely packed group called the nucleus of the atom. Electrons revolve at high speed around the nucleus at relatively great distances from it. An atom can be visualized as a miniature solar system in which the electrons revolve around the nucleus much the same as planets revolve around the sun.

A gravitational force exists between the proton and electron of an atom. An electrical force also exists. A gravitational force always attracts, but an electrical force can either attract or repel. This electrical force is explained by ascribing an electrical property called charge to protons and electrons. A proton is arbitrarily said to have one unit of positive (+) charge, and an electron one unit of equal but opposite negative (-) charge. During a state of rest, protons repel other protons, electrons repel other electrons, but a proton attracts and is attracted by an electron. Hence, the rule that like charges repel, and unlike charges attract each other. Neutrons, as the name implies, are electrically neutral, having no charge, and are neither attracted nor repelled by a proton or electron.

In addition to the electrical forces between charged particles at rest, other forces exist which depend upon the relative motion of the particles. These are called magnetic forces, and always accompany moving electrical charges. Thus, electricity and magnetism are not separate phenomena; both aris from the properties of electrical charges.

A conductor is material containing charges which are free to move under the influence of an electric field. If the electric field is maintained within the conducting circuit, the motion of the free charges is continuous. This motion is called current. If the field is always in the same direction, the resulting current is called direct current. If the field periodically reverses direction, the current also reverses and is called an alternating current.

Figure 8-1 shows two metal plates which are connected by a wire broken by a switch S. The air between the two plates acts as an insulator. Suppose that the two plates receive from an external source a concentration of positive and negative charges. An electric field then exists in the air between the plates. The charges are isolated on the plates by the absence of a conducting path, and hence this arrangement, known as a capacitor, provides a convenient storage of electric charges. If the switch is closed, a current flows in the wire in the direction shown until the electric field is exhausted and the charges on the plates are equalized.

When electric charges are in motion, as when a current is flowing in a conductor, a magnetic field forms around the conductor. Once formed, the magnetic field surrounding all portions of the conductor is constant in direction and intensity if the generating current is also constant. If the current carrying wire is wound into a coil, called an inductor (fig. 8-2), the resulting magnetic field is intensified in proportion to the number of turns. The greater the inductance, the stronger the magnetic field for a given current.

Suppose that a circuit contains both capacitance and inductance, or a combination of circuits as in figure 8-1 and 8-2. When the switches are closed, the energy in the electrical field at the capacitor causes a current to flow in the inductor, thereby creating a magnetic field. This continues until the capacitor is completely discharged. All the energy now resides in the

10543

AC.104

Figure 8-1.—Capacitance.

AC.105

Figure 8-2.—Inductance

magnetic field. When the current ceases, there is nothing to sustain the magnetic field, which promptly collapses, returning the energy to the circuit. This recharges the capacitor and the energy of the circuit has now been transferred from the magnetic field back to the electric field. This type of circuit is known as an oscillating circuit and the sequence repeats itself indefinitely. The oscillating circuit lies at the heart of radio, because it provides a source of alternating electric and magnetic fields and a means of controlling the frequency of oscillations known as tuning.

Most of the energy stored in the electric field of a capacitor or the magnetic field of an inductor is restored to the circuit when the capacitor has become discharged or when current ceases to flow in the inductor. These fields expand and contract at nearly the speed of light, which is approximately 186,000 miles per second. At very low frequencies there is ample time for the restoration of energy to take place. However, as frequency increases, the recurring cycles become faster. When the time needed for the field to expand and collapse is more than about one-half cycle, some of the energy becomes detached and continues to radiate into space at approximately the speed of light. Such radiating energy, called electromagnetic radiation, is the link between a radio transmitter and receiver.

BASIC RADIO PRINCIPLES

Radiated electromagnetic energy suitable for radio communication is called a hertzian wave. The wave is named for an early German physicist and mathemetician named Hertz, who introduced the theory of the kinetic energy of an electrical current. Hertz's discoveries, along with many other discoveries, laid the basis for the development of radio telegraphv.

The hertzian wave can be represented by a sine curve as shown in figure 8-3. The top of the wave represents the maximum positive value, and the bottom represents the maximum negative value. Either maximum may be called a peak. Wave length is the distance between corresponding points on consecutive waves as shown in figure 8-3. It is the distance a wave travels during one cycle. Frequency is the number of cycles that occur per second, stated in terms of hertz, abbreviated Hz; thousands of cycles per second stated in terms of kilohertz, abbreviated kHz; or millions of cycles per second stated in terms of megahertz, abbreviated MHz. The range of frequencies involved, called the radio spectrum, extends from approximately 10kHz to 300,000 MHz as shown in table 8-1.

AC.106

Figure 8-3.—Hertzian wave nomenclature

AC.107

Figure 8-4.—Types of radio waves.

A hertzian wave, as previously indicated, is an oscillating electromagnetic field. A continuous series of such waves of like characteristics is called a continuous wave (CW). (See fig. 8-4 (A).) Such a wave can be used in Morse code transmissions, being keyed so that the signal is interrupted when desired. (See fig. 8-4 (B).) A continuous wave may be modified in accordance with some characteristics of an audio frequency signal, such as that produced by the human voice. When thus used, it is called a carrier wave. The process of modifying the carrier wave in this manner is called modulation. After this has taken place, the carrier wave may be called a modulated carrier wave. (See fig. 8-4 (C).) When this form of radio transmission is used, the transmitting station generates the carrier wave and modulates it by the message to be conveyed. The receiver demodulates the incoming signal by removing the modulating signal and converting it to its original form.

There are four principal kinds of modulation. In amplitude modulation (AM) the amplitude (fig. 8-3), of the carrier wave is altered. This is the most widely used form of modulation. In frequency modulation (FM) the frequency of the carrier wave is altered. This is used in some voice communications and commercial broadcasting and has an advantage of being nearly static free. In phase modulation the phase (amount by which the beginning of a cycle is displaced from a reference origin) is altered. This is similar to FM and has some engineering advantages. In pulse modulation (PM) very

Frequency range	Name of the range	Symbol
Below 30 kHz	Very low frequency	VLF
30-300 kHz	Low frequency	LF
300-3,000 kHz	Medium frequency	MF
3-30 MHz	High frequency	HF
30-300 MHz	Very high frequency	VHF
300-3,000 MHz	Ultrahigh frequency	UHF
3,000-30,000 MHz	Superhigh frequency	SHF
30,000-300,000 MHz	Extremely high frequency	EHF

10545

short bursts of carrier wave signals are transmitted, followed by relatively long periods during which no signal is transmitted. PM is used in RADAR, DME, and radio teletype.

With amplitude modulation, two sidebands are radiated, the frequencies of which are the sum and difference, respectively, of the carrier and modulating frequencies. The intelligence is carried only on the sidebands. In single sideband (SSB) transmission the carrier and one of the sidebands are suppressed, producing narrow bandwidth transmission. Bandwidth is the amount of radio spectrum required for transmission, including the carrier wave and both sidebands when present. SSB transmission is desirable in that it effects economy in the use of limited frequency bands and in power.

RADIO TRANSMITTER

A radio transmitter consists essentially of a power supply to furnish direct current; an oscillator to convert direct current into radio frequency oscillations (the carrier wave); an amplifier to increase the output of the oscillator; a device for controlling the frequency of the generated signal; and, for most transmitters, a modulator to produce modulation of the carrier wave. (See fig. 8-5.) In addition, an antenna is needed to project the electromagnetic radiation into space. An antenna may be nondirectional or directional depending upon the design or arrangement of antennas, called an array. Reflectors are also used to reflect some of the radiated energy in a desired direction.

RADIO RECEIVER

When an electromagnetic field passes a conductor such as an antenna, a current is induced in the conductor, which thereby becomes a generator of radio frequency power. A radio receiver is a device which accepts the power thus generated by an antenna, and transformed it into usable form. The output of receivers most used by AC's is presented aurally via earphones or a loud speaker, or visually on a cathode ray tube as in RADAR or DF.

A radio receiver consists essentially of electrical components capable of doing four things as follows:

1. Selecting a signal of a single frequency from among the thousands existing together in the receiving antenna.
2. Amplifying the selected signal without distortion until it is sufficiently powerful to actuate succeeding devices within the receiver.
3. Demodulating any modulated signal so as to produce a new signal of audible or other usable frequency.
4. Amplifying that signal still further until, at the output of the receiver, it can operate the devices which present the signal in usable form. (See fig. 8-6.)

VHF/UHF OMNIDIRECTIONAL RANGES

The omnidirectional facility derives its name from the Latin word omnis, meaning all. Hence

AC.108

Figure 8-5.—Radio Transmitter.

10546

AC.109

Figure 8-6.—Radio receiver.

the omni facilities produce directional guidance in all directions. Theoretically speaking, an infinite number of courses are produced by these facilities, but in actual practice only 360 are usable under optimum conditions. Courses produced by omni facilities radiate from the station like spokes from the hub of a wheel and are called RADIALS. It is important to remember that the radials are always FROM the station.

PRINCIPLE OF OPERATION

The principle of the omnidirectional facility is based on the comparison of the phase difference between two radiated audio frequency signals, the difference in phase varying with change in azimuth. One of the two signals is nondirectional. It has a constant phase throughout 360 degrees of azimuth and is called the reference phase. The other signal rotates at a speed of 1,800 rpm, varies in phase with azimuth, and is called the VARIABLE phase.

The rotating signal is initially set so that at magnetic north both the reference and the variable signals are exactly in phase. In all other directions, the positive maximum of the variable signal will occur at some time later than the maximum of the reference signal. The fraction of the cycle which elapses between the occurrence of the two maximums at any point in azimuth identifies the azimuth angle of that point. (See fig. 8-7.)

For an analogy to help visualize the method of determining bearing from the transmitter let

AC.110

Figure 8-7.—Comparison of reference and variable phase.

us use as an example, a rotating light beacon. Suppose that an additional light flashes each time the light beam sweeps past magnetic north and the beacon rotates clockwise at 6 rpm (one revolution each 10 seconds or 36 degrees per second).

To determine our direction from the beacon, we could use a stopwatch, starting the watch at the instant we see the start of the flash and stopping it when the rotating beam sweeps past our position. Then, by multiplying the number of seconds shown on the stopwatch by 36, we can obtain our magnetic bearing from the beacon. Suppose that exactly 5 seconds elapse from the start of the flash until the rotating beam flashes past us: 5 x 36 = 180. From this we determine that our bearing from the beacon is 180 degrees.

If we move our position to the right (counterclockwise), the elapsed time interval would be shorter; hence, our bearing would be something less than 180 degrees. The reverse would be true if we moved our position to the left (clockwise). In effect, the reference and variable voltages of the omni facility provide the same information electronically that the flasher and the beacon supply visually in this example.

RECEIVING EQUIPMENT

The basic function of the airborne receiving equipment is to measure the phase angle between the reference voltage and the variable voltage. As described previously, each point or degree of azimuth radially from the ground transmitter has a definite, fixed phase difference between the reference and the variable signals. Therefore, it our receiving equipment can translate and provide in readily usable readings on the instrument panel the phase difference existing at the receiving position, a bearing from the transmitter is obtained. Likewise, if out equipment can be adjusted to any desired bearing (or phase difference), and indicate when the aircraft has reached that bearing, we may preset courses, then fly to and continue along them. That is exactly what the receiving system is designed to do, and a great deal of information is available to the pilot taking advantage of all its possibilities.

DISTANCE MEASURING EQUIPMENT (DME)

Distance and direction from a known ground point are two items of information necessary to establish position in air navigation and assist the air traffic controller to effectively maintain separation. Until the advent of equipment for measuring distance, a pilot could find his bearing toward a selected navaid; but in order to determine his actual position (bearing and distance), it was necessary to tune to another facility and determine his position by cross-reference methods. This was time consuming. By use of the present-day distance measuring equipment the pilot has both the bearing and distance from the station displayed on the indicators.

Principles of Operation

Distance measuring capability requires special equipment in the aircraft and on the ground. The airborne equipment is known as the INTERROGATOR and the ground equipment is called the TRANSPONDER. In the operation of distance measuring equipment, paired pulses at a specific spacing are sent out from the aircraft (this is interrogation) and are received at the ground station. The ground station (transponder) then transmits paired pulses back to the aircraft at a different pulse spacing and on a different frequency. The time required for the round trip of this signal exchange is measured in the airborne unit and is translated into distance (nautical miles) from the aircraft to the ground station.

Operating in the UHF band on the line-of-sight principle, distance measuring equipment furnishes distance information with a very high degree of accuracy. DME measures slant distance rather then horizontal distance over the ground. Except in the immediate vicinity of the transponder and at a relatively high altitude, the navigation error introduced by the slant measurement is minor and usually may be ignored.

TYPES OF OMNIRANGES

Several types or combinations of VHF/UHF omni facilities are in operation today; therefore, careful use of terminology referring to these facilities is necessary. The omni facilities and their operating frequencies are as follows:

1. VOR. VHF omnidirectional radio range which provides bearing (direction) information. VOR facilities operate on frequencies between 108.0 MHz and 118.0 MHz.

10548

2. VOR/DME. VHF azimuth information and UHF distance information furnished from collocated components. Frequency pairing allows the use of a single receiver tuning selector capable of simultaneously selecting a paired VOR and DME receiver frequency.

3. TACAN. UHF omnidirectional radio range which provides direction and distance information. TACAN facilities operate on frequencies between 960 mc and 1,215 mc. VOR receivers are unable to receive navigational signals from TACAN facilities.

4. VORTAC. A combination of VOR and TACAN. This facility provides azimuth navigational information on VHF (108-118 mc) and azimuth and distance navigational information on UHF (960-1,215 mc). Aircraft having complete TACAN airborne equipment can receive both distance and azimuth information from the TACAN portion. Aircraft equipped with VOR receivers use the azimuth information from the VOR and must obtain distance information from the TACAN portion. This is accomplished through single receiver tuning selection of paired frequencies as with VOR/DME.

RECEPTION DISTANCE

Like all VHF/UHF transmissions, omni facility signals follow an approximate line-of-sight course. (See fig. 8-8.) Therefore, reception distance increases with an increase in the altitude of an aircraft. Since the reliable operating range is about 40 miles at minimum en route altitude (1,000 ft above terrain), omni facilities are spaced approximately 90 miles apart to assure navigation coverage over an airway. Due to the operational band of the omni facilities, they are relatively free of atmospheric and precipitation static.

AC.111

Figure 8-8.—Line-of-sight transmission characteristics.

CLASSIFICATION

VOR, VORTAC, and TACAN navaids are classed according to their operational use. There are three classes as follows:

T . . . . . Terminal
L . . . . . Low altitude
H . . . . . High altitude

Table 8-2 shows the normally anticipated altitude and interference-free distance service. It is apparent from the table that this is not maximum range of the facility. Use of these facilities beyond the prescribed limitations is not intended, and may therefore result in undependable or inadequate indications in the aircraft.

Class	Altitudes	Distance (miles)
T	12,000' and below	25
L	Below 18,000'	40
H	Below 18,000'	40
H	14,500' -- 17,999'	100*
H	18,000' -- FL 450	130
H	Above FL 450	100

*Applicable only within the contiguous 48 states.

IDENTIFICATION

VOR's are identified by two methods consisting of the ground facility transmitting one of the following:

1. A 3-letter identifier in Morse code.
2. A recorded automatic voice identification announcing the name of the facility followed by the statement V-O-R.

Identification of VOR facilities is transmitted continuously except when interrupted by an actual

of the scope. These guides or markers provide range and azimuth (bearing) of a target. Some systems present additional information that gives the operator the relative height of the target.

Markers are also used on equipment other than radar, for example—electronic countermeasures, loran, oscilloscopes, and many others. In these equipments, markers are used to determine pulse width, pulse spacing, pulse amplitude, and various other functions.

Early radars depended on the linearity of the scope sweep for accuracy in range. A rough range scale was etched on a transparent plastic plate and this was placed on the face of the scope. Present-day radars obtain range markers from a range marker circuit. This circuit consists of a stable oscillator that generates accurately spaced range markers which are used to modulate the electron beam in a PPI type scope. This type presentation causes intensity type markers to appear.

An A-scope may also utilize intensity type markers or the markers may be applied to the deflection circuits. The application of the marker to the deflection circuits causes pulse type markers to appear on the scope.

FIXED RANGE MARKER

This circuit uses a gated type ringing oscillator which produces range marks that are synchronized with the sweep. A circuit that illustrates this system is shown in figure 14-18.

The gating tube V1, because of positive bias, is normally conducting and producing a steady flow of current through L1. The flow of current through L1 maintains a magnetic field around the coil; thus, the tank circuit composed of L1 and C2 cannot oscillate. Simultaneously with the starting of the scope sweep a negative square wave is applied to the grid of V1, cutting the tube off and causing the magnetic field around L1 to collapse. The collapsing of this field shock-excites the oscillator. The circuit continues to oscillate throughout the duration of the negative square wave. The values of L and C, in the series-fed Hartley oscillator, are so chosen that the duration of each cycle of oscillation is equal to the time between the desired range marker spaces. The leading edge of each negative oscillation produces a range marker in the output of the circuit. V2 replenishes the losses of the tank circuit, thereby maintaining the amplitude of oscillation.

Figure 14-18.—Ringing oscillator range marker.

1052

voice transmission on the voice feature of the navaid, or during periods of maintenance, in which case the identification of the facility is removed.

TACAN's are identified by ground facility transmission of a 3-letter identifier in Morse code at regular intervals of 37.5 seconds.

VORTAC identification requires identification of both the VOR and TACAN portions of the facility. The procedure is basically the same as for individual facilities except they are interlocked; i.e., the VOR identification is continuous except at regular intervals of every 37.5 seconds when the TACAN is identified. Where the recorded automatic voice identification is used for the VOR portion, it consists of the name of the facility followed by the word VORTAC.

VOR RECEIVER CHECKS

Federal Air Regulations Part 91 (covered in chapter 9 of this training manual), provides for certain VOR equipment accuracy checks prior to flight under instrument flight rules (IFR). The FAA has provided the following means of checking VOR receiver accuracy:

1. VOR test facility (VOT).
2. Certified airborne checkpoints.
3. Certified checkpoints on the airport surface.

The VOR test facility (VOT) transmits a test signal for VOR receivers which provides a convenient and accurate means to determine the operational status of their receivers.

Airborne and ground checks consist of certified radials that should be received at specific points on the airport surface, or over specific landmarks while airborne in the immediate vicinity of the airport.

Should an error in excess of plus or minus 4 degrees be indicated through the use of the ground check, or plus or minus 6 degrees using the airborne check, IFR could not be attempted without first correcting the error.

In addition to the above procedure, the Navy has established checkpoints on taxiways, usually in close proximity to the warmup area, or those used just prior to taxiing on the runway in use. These checkpoints consist of a position on the taxiway, marked by a yellow triangle painted on the surface, and a painted sign adjacent to the taxiway that indicates the distance and bearing to the TACAN/VOR from a position directly over the triangle. (See chapter 11.)

CAPABILITIES AND LIMITATIONS

The VOR and TACAN characteristics are similar with the exception of VOR providing bearing information only and operating in the VHF frequency band. Since TACAN is widely used throughout the Navy as a primary navaid, no reference is made to VOR in this section.

The TACAN system employs 126 two-way operating channels of 1 megacycle spacing within the frequency range of 960 to 1215 megacycles. Bearing information is available to an unlimited number of aircraft within range (line or sight) of the facility. Distance information is also limited to line of sight and normally extends from 0 to 195 miles. Newer equipment may provide distance information to 300 miles. A ground facility will reply to as many as 120 interrogations for distance information simultaneously. Thus it can be said that each of the 126 TACAN channels available will provide full service (bearing and distance) to as many as 120 aircraft simultaneously.

TACAN bearing accuracy is plus or minus 3/4 of 1 degree. The distance accuracy is about plus or minus 600 feet plus 2 percent of the distance measured.

Atmospheric conditions above 50,000 feet are such that the high voltages within the equipment are sufficient to cause arcing. Therefore, TACAN operation is limited to altitudes up to 50,000 feet.

On later models of airborne TACAN equipment, air-to-air ranging has been added which provides distance information between airborne TACAN radio sets. To accomplish this function, pilots of the aircraft concerned must agree upon selection of two different TACAN channels which are separated by exactly 63 megacycles. Channels 15 and 78, for instance, constitute one channel pair which is necessary for the system to work. If such a capability exists, an airborne TACAN radio set can transmit distance reply signals to interrogations from as many as five other sets simultaneously. At the same time, the set will receive replies to its own interrogations from all five other sets. However, only the distance to one other set can be displayed on the aircraft's distance indicator. No bearing information is available between aircraft when the air-to-air ranging feature of the equipment is selected. Also, ground-to-air information is not available when the air-to-air feature is selected.

Figure 8-9, is an example of the visual display provided the pilot of an aircraft receiving full service from a TACAN facility. Figure 8-10 is an example of the visual display provided the pilot when the air-to-air feature is selected.

AIRCRAFT INSTRUMENTATION

The purpose of this section is to provide the Air Controlman with an idea of the practical use of TACAN and the basic aircraft instruments involved. There are several types of instruments, or modifications thereof, available, and new ones are being produced continuously to provide Navy pilots with the best possible navigation assistance. The instruments depicted here are not to be considered as standard in Navy aircraft. VOR is not referred to due to similarity of operation with the exception that VOR provides bearing information only and operates within the VHF frequency band instead of the UHF band as does TACAN.

Figure 8-11 shows a TACAN control box and the various switches. The control system labeled CHAN allows a pilot to select one of the 126 operating TACAN channels available. The switch at the upper right hand side of the control box allows a pilot to turn the TACAN set off, receive only (REC) which provides bearing information only, transmit/receive (T/R) which provides both bearing and distance information, or air-to-air ranging (A/A) which provides distance information between airborne TACAN radio sets. Th volume control selects the desired volume level of the identification of the TACAN channel selected. This identification is the 3-letter Morse code identification of the TACAN and is heard in the pilot's radio headset.

AC.112

Figure 8-9.—TACAN system.

AC.113

Figure 8-10.—Air-to-air ranging.

10551

AC.114

Figure 8-11.—TACAN control box.

Figure 8-12, shows three basic instruments used for TACAN air navigation. They are as follows:

1. The range indicator, which displays distance in nautical miles to the TACAN station selected by the channel selector.

2. The course indicator, which displays the following:

a. The relative position of the course selected (the window labeled course) to the aircraft (vertical bar).

b. Whether the selected course will take the aircraft TO or FROM (TO-FROM indicator on the left side of the instrument) the station.

c. The relationship of the aircraft's heading (vertical needle) to the course selected.

3. The radio magnetic indicator (RMI), which displays the following:

a. The magnetic heading of the aircraft (rotating compass card).

b. The relative bearing of the TACAN station from the aircraft (large needle with the number 2 on it).

NOTE: There is another small needle used on the RMI for Automatic Direction Finding (ADF), which is discussed later in this chapter, but is not shown in figure 8-12.

Figure 8-13 is an example of maintaining flight along a specified TACAN radial by correcting for wind drift.

Figure 8-12 is the actual instrument display of the aircraft's position No. 1 in figure 8-13 as follows:

1. The range indicator shows that the aircraft is 60 miles from the TACAN station.

2. The course indicator shows that the aircraft is on the selected course (060) which will take it TO the station.

3. The radio magnetic indicator (RMI) shows that the aircraft's magnetic heading is 060 and the TACAN is directly ahead of the aircraft.

At position No. 2 of figure 8-13, wind has blown the aircraft off the radial. The instruments indicate this as follows:

1. The range indicator shows that the aircraft is now 50 miles from the TACAN station.

2. The course indicator shows:

a. The selected course (060) which will take the aircraft TO the station is left of the aircraft's position (vertical bar).

b. The aircraft's heading is parallel to the selected course (vertical needle).

AC.115

Figure 8-12.—Range indicator, course indicator, and radio magnetic indicator.

10552

AC. 116

Figure 8-13.—Flying a TACAN radial.

3. The RMI shows that the aircraft's heading is still 060 magnetic, but the TACAN station now bears left of the aircraft's nose.

The pilot must apply corrections to return the aircraft to the desired radial. Position No. 3 shows the instrument display after the corrections have been made as follows:

1. The range indicator shows the aircraft is now 40 miles from the TACAN station.

2. The course indicator shows that the selected radial (060) is stall left of the aircraft's position (vertical bar), and the heading of the aircraft will intercept or is toward the selected course (vertical needle).

3. The RMI shows that the pilot has changed the magnetic heading to 030 and the TACAN station now bears to the right of the aircraft's nose.

Position No. 4 shows the aircraft back on course with a corrected heading to maintain such course as follows:

1. The range indicator shows the aircraft is now 10 miles from the TACAN station.

2. The course indicator shows the following:

a. The aircraft is back on the selected radial (vertical bar) which will take it TO the station.

b. The aircraft's heading is left of the course selected to compensate for the wind (vertical needle).

3. The RMI shows the aircraft's magnetic heading is 050 and the TACAN station bears right of the aircraft's nose.

When the aircraft passes over the station, distance on the range indicator will commence to increase, the vertical bar on the course indicator will fluctuate from side to side momentarily, the TO-FROM indication on the course indicator will change to FROM, and the needle on the RMI will rotate aimlessly, then stabilize 180 degrees from the bearing approaching the station, or point aft of the aircraft to the TACAN station. The reason for the course indicator and RMI TACAN needle fluctuation is a large cone of ambiguity directly over all TACAN stations in which no bearing information is received. Therefore, the instruments which use bearing information will not settle down until an aircraft has passed through the cone. However, distance information is constant; and since it is slant range, there will be a reading of distance directly over the TACAN station which indicates the vertical distance or altitude of the aircraft. (See fig. 8-14.)

AC.117

Figure 8-14.—TACAN station passage.

10554

TACAN may also be used to maintain a constant distance, called ARC, from a TACAN station. To accomplish this a pilot would, after arriving at the desired distance (ARC), select a magnetic heading on the RMI to cause the RMI TACAN needle to point off the aircraft's wing or 90 degrees relative to the TACAN station. Then the magnetic heading would be altered slightly to maintain a constant distance or fly the ARC, and constant relative bearing to the TACAN station.

RADIO BEACONS

Several types of radio beacons are used as aids to aircraft navigation. The discussion in this chapter includes nondirectional beacons, ADF procedures, and marker beacons.

NONDIRECTIONAL RADIO BEACONS (NDB)

A low or medium-frequency radio beacon transmits nondirectional signals whereby the pilot of an aircraft equipped with a loop antenna can determine his bearing and "home" on the station. These navaids normally operate in the frequency range of 200 to 415 kHz and transmit a continuous carrier with a continuous keyed identification except during voice transmissions.

When a radio beacon is used in conjunction with the ILS markers, it is called a compass locator. ILS systems are discussed later in this chapter.

All radio beacons except the compass locators transmit a continuous three-letter identification in code. Compass locators transmit a continuous two-letter identification in code.

Voice transmissions are made on radio beacons unless the letter W (without voice) is included in the class designator. Radio beacons are subject to disturbances that result in ADF needle deviations, signal fades, and interference from distant stations during night operations. Table 8-3 shows the classification and normal usable distances of NDB's.

Class	Power (watts)	Distance (miles)
Compass Locator	Under 25	15
MH	Under 50	25
H	50 -- 1999	50
HH	2000 or more	75

AUTOMATIC DIRECTION FINDING (ADF)

Although many new types of direction finding and homing equipment are coming into widespread use, the radio compass still remains a basic and important piece of equipment for homing, tracking, course interception, time/distance checks, and similar purposes. Therefore, a brief description of the basic method utilized in an ADF orientation is included so that the Air Controlman may visualize the "pilot's position" during an ADF orientation.

When the pilot is flying ADF, the problem of orientation is solved automatically. The 0-180 degree axis of the radio compass indicator is alined with the longitudinal axis of the aircraft. Thus you can think of 0 degrees on the radio compass dial as representing the nose of the aircraft, while 180 degrees on the radio compass dial represents the tail of the aircraft. The radio compass needle always points toward the station. This means that when the radio compass indication is between 0 and 090 degrees, the station is ahead and to the right of the aircraft. When the radio compass points to a reading between 180 and 190 degrees, the station is behind and to the right. A reading between 180 and 270 degrees shows that the station is behind and to the left, while a reading of between 270 and 360 degrees shows that the station is ahead and to the left. The radio compass needle points to the number of degrees the pilot must turn in a clockwise direction to head directly toward the station. This is called the relative bearing of the station.

By adding the relative bearing of the station and the magnetic heading of the aircraft, the pilot can determine the magnetic bearing of the station. This establishes a line of position from the aircraft to the station. By looking at figure 8-15, you can see that the aircraft is approaching the station from the southwest. The magnetic bearing of the station is 060 degrees. For the sake of simplicity, we will assume that there is no wind drift, so a magnetic heading of 060 degrees is holding the aircraft on this bearing. The radio compass indicates the relative bearing of the station—the angle measured clockwise from the nose of the aircraft to the station. In this case, the relative bearing is 0 degrees.

AC.118

Figure 8-15.—Inbound bearings to station X.

MARKER BEACONS

Marker beacons serve to identify a particular location in space along an airway or on the approach to an instrument runway. This is done by means of a 75-MHz transmitter which transmits a directional signal to be received by aircraft flying overhead. Three classes of markers are now in general use—FM, LFM, and the Instrument Landing System (ILS) marker beacons.

The class FM fanmarkers are used to provide a positive identification of positions at definite points along the airways. The transmitters have a power output of approximately 100 watts. Two types of antenna array are used with class FM fanmarkers. The first type used, and generally referred to as the standard type, produces an elliptical-shaped pattern, which at an elevation of 1,000 feet above the station is about 4 miles wide and 12 miles long. At 10,000 feet the pattern widens to about 12 miles wide and 35 miles long. (The long axis lies across the airway.)

The second array produces a dumbell or bone-shaped pattern, which, at the "handle" is about 3 miles wide at 1,000 feet. The bone-shaped marker is preferred at approach control locations because the narrow pattern provides a more accurate position.

The class LFM or low-powered fanmarkers have a rated power outupt of 5 watts and are usually located within 5 miles of the station with which they are associated. The antenna array produces a circular pattern which appears elongated at right angles to the airway due to the directional characteristics of the aircraft receiving antenna.

ILS marker beacon information is included under the heading "Instrument Landing System" in this chapter.

At certain installations where the fanmarker is located off the airways and the radio beacon is installed at the fanmarker site, is the FMHW. The FMHW is a combination of two facilities, for the specific purpose of allowing aircraft to proceed directly to the marker by means of the radio compass. The FMHW consists of the following:

1. FM—A fanmarker, bone or elliptical, 100 watts.
2. MH—A low-powered radio beacon, less than 50 watts.
3. W—Designates without a voice facility.

INSTRUMENT LANDING SYSTEM

One of the most important problems in the achievement of all-weather flight reliability has been the development of a system for landing aircraft by instruments. This development has gradually evolved into the present Instrument Landing System, commonly known as ILS.

ILS was originally known as the 3-element system and has three main components:

1. A localizer radio beam to furnish directional guidance to the airport runway.
2. A glidepath radio beam to furnish vertical guidance down the correct descent angle to the runway.
3. Fanmarkers to provide accurate radio fixes along the approach course.

While these three elements are being improved, there are several supplementary elements being incorporated to further increase the utility and safety of the system. Compass locator stations have been added to assist in holding procedures and in tracking the localizer course. High-intensity approach lights have been installed to furnish visual guidance to the runway under extremely low visibility conditions. PAR is another added feature with which to monitor the actual flightpath of aircraft using ILS.

10556

To utilize the localizer associated with ILS, an aircraft must be equipped with VHF receiver capable of receiving frequencies in the 108- to 112-MHz band. The aircraft must also be equipped with a course indicator to display the information received.

The structure housing the localizer unit of the ILS is located on the extended centerline of the instrument runway of an airport. It is located far enough from the end of the runway to prevent it from being classed as a hazard.

This unit radiates a field pattern directly down the centerline of the runway toward the fanmarkers. It also directs another field pattern in the opposite direction. These patterns are called the front and back courses, respectively. (See fig. 8-16.)

Utilizing the front course for an ILS approach is desirable since glidepath information is displayed only on this course. The back course may also be used, but since no glidepath information is available, the approach minimums will be considerably higher.

The localizer transmitter is designed to provide an oncourse signal at a minimum distance of approximately 25 miles from the runway at a minimum altitude of 2,000 feet. The power of this transmitter is approximately 100 watts. To produce the oncourse signal, the radiated field pattern is modulated at two different frequencies. The right side, looking from the outer marker toward the transmitter, is modulated at 150 Hz. This is identified as the blue sector on maps or charts. The left side is modulated at 90 Hz and is identified as the yellow sector. The oncourse is the point of equisignal strength between the radiated pattern.

Each localizer is identified by a 3-letter code group preceded by an "I" designator; for instance, I-MIA or I-DAL. Most ILS installations include a voice facility on the localizer frequency. This voice faclity is used for the transmission of approach control instructions from the airport control tower.

The glidepath unit is housed in a building approximately 1,000 feet from the approach end and approximately 400 feet to the side of the centerline of the instrument runway. The beam projected by the glidepath transmitter is essentially the same as would be the localizer beam operating on its side. The upper side of the beam is modulated at 90 Hz and the lower side at 150 Hz.

The glidepath projection angle is normally adjusted between 2 1/2 degrees and 3 degrees above the horizontal so that it interesects the middle marker at about 200 feet and the outer marker at about 1,100 feet above the runway elevation.

In addition to the desired course, all glidepath facilities inherently produce 5 additional courses at high vertical angles (the lowest of these courses at approximately 16 degrees above the horizontal). However, provided pilots are properly indoctrinated in glidepath instrumentation and follow procedures correctly, these high angles will not be encountered and will cause no difficulty in glidepath navigation. (See fig. 8-17.)

The glidepath transmitter operates in a frequency band of 328.6 to 335.4 MHz, with a reception range of approximately 25 miles and a power output of 100 watts.

Every localizer frequency has a corresponding glidepath frequency. The frequency selector control is designed to switch the glidepath receiver to the corresponding frequency automatically when the pilot selects the proper localizer frequency, provided the aircraft is

AC.119

Figure 8-16.—ILS localizer installation.

AC.120

Figure 8-17.—ILS glidepath and marker installation.

10557

equipped with a glidepath receiver. This process is known as PAIRED FREQUENCIES.

The markers used with the ILS are low-powered fanmarkers of approximately 2 watts output, operating on the fanmarker frequency of 75 mc and radiating the same vertical elliptical-shaped pattern.

The outer marker is located approximately 4 to 7 miles from the instrument runway and is alined on the front course of the ILS.

The middle marker is located approximately 3,500 feet from the approach end of the runway, between the runway and the outer marker.

Certain civil and military aircraft are equipped with ILS marker receivers which are used in connection with ILS facilities. They are usually equipped with purple and amber lights mounted on the instrument panel of the aircraft. Although all ILS markers are on the same frequency, the different lights are designed to operate independently, depending on the modulation frequency (tone) of the signal being received. A 400 hertz band-pass filter is included in the purple light hookup and a 1,300-hertz filter, for the amber light. These filters are intended to pass only the particular modulation frequency for which they are designed. Thus, when the aircraft is over an outer marker (400-hertz tone), the purple light will flash two dashes per second. When the aircraft is over a middle marker (1,300-hertz tone), the amber light will flash alternate dots and dashes.

The modulated tone signal is heard in the headset, and at the same time the visual signal is displayed by the marker beacon light.

The compass locator is a low-powered (25-watt) nondirectional radio beacon, operating in the 200- to 415-kHz frequency band. It is employed as an aid in the following:

1. Transition from en route to ILS, flying a homing path direct to the outer marker from the designated radio fix or facility.
2. Flying a holding pattern by keeping the pilot advised at all times of his position relative to the outer marker.
3. "Tying down" and tracking the localizer course.
4. Determining when the markers are passed. This is particularly useful in case of failure of the fanmarker equipment.

A 2-letter identifier is used for the identification of the compass locator (LOM and LMM). The two letters are derived from the 3-letter location identifier.

The first and second letters of the 3-letter location identifier are assigned to the front course outer marker compass locator (LOM), and the second and third letters are assigned to the front course middle marker compass locator (LMM).

Example: Oklahoma City, Okla.-OKC LOM-OK LMM-KC.

When used in conjunction with ILS, compass locators are installed at the outer and/or middle marker location. They are designed for use with automatic direction finding (ADF) equipment in the aircraft.

NAVAID MONITORS

A malfunction of navaid equipment could place a pilot in a critical position; therefore, it is necessary that some automatic means be provided for continuously checking a navaid system.

Normally, the control tower is responsible for monitoring navaids at an air station. This is accomplished by electronic navaid monitoring devices located in the tower. Most monitor equipment is similar, in that it provides both a light and an aural alarm to indicate that a particular navaid is malfunctioning. Some monitor equipment provides for an automatic changeover to standby navaid equipment when the main system has failed. Other equipment requires that the standby equipment be "dialed" on, which is a method similar to dialing a telephone with certain codes being dialed for certain functions.

When an alarm system of a navaid monitoring device goes off, the Air Controlman on duty in the tower should attempt to get the standby equipment in operation, if not automatic. Then he should notify the technician responsible for maintenance of the navaid equipment to provide for rapid repairs.

If the navaid has to be shut down or is unreliable, control tower personnel should immediately notify the appropriate persons or facilities, which is determined locally. These generally include the duty section leader, the appropriate duty officer, the technician who will repair the equipment, the associated approach control if not located in the tower, and the ARTCC in whose area of responsibility the station is located.

10558

10228

AERONAUTICAL LIGHT BEACONS

The aeronautical beacon is a visual navaid displaying flashes of white and/or colored light, which is used to indicate the location of airports, landmarks, and hazards to air navigation. The principal light used is a rotating beacon of relatively high intensity.

The color or color combination displayed by a particular beacon tells whether the beacon is indicating a landing place, landmark, or hazard.

COLOR AND MEANING OF LIGHT BEACONS

The colors and color combinations of aeronautical light beacons and their meaning are as follows:

1. A rotating beacon displaying alternating white and green flashes indicates that the beacon is at or within 2 miles of a lighted airport or landing field.

2. Military lighted airport rotating beacons display alternating white and green flashes, but the white flash has dual peaked (two quick) flashes to differentiate from civil beacons.

3. Green flashes alone, usually coded, from a code beacon (not a rotating beacon) used by itself, means that the code beacon is located at or beside a lighted airport. When a rotating white and green beacon is located more than 5,000 feet from an airport or landing field, the green-flashing code beacon is used to show more exactly the location of the landing area.

4. A rotating beacon displaying alternating white and yellow flashes indicates the presence of a lighted water airport (sea drome) at or within 2 miles of the beacon site.

5. Yellow flashes alone, usually coded, from a code beacon (not a rotating beacon) used by itself means that the code beacon is located at or beside a lighted water airport. When a rotating beacon showing alternate white and yellow flashes is located more than 5,000 feet from a water airport, the yellow flashing code beacon is used to show more exactly the location of the landing area.

6. A rotating beacon displaying alternating white and red flashes indicates the location of a natural or manmade landmark.

7. A rotating beacon displaying red flashes alone indicates the presence of an obstruction or obstructions to air navigation, or an area on the ground used for purposes hazardous to air navigation.

8. Steady burning red lights are used near airports to mark obstructions, and are also used to supplement flashing lights in marking enroute obstructions.

10559

10228

The peaking amplifier V3, that is normally conducting, is cut off by the oscillator's negative output. A high positive voltage at the plate of V3 is produced by the collapsing magnetic field around L6. Oscillations across L6 are prevented by damping resistor R7, thereby preventing possible double range markers on the scope. Positive oscillation of the grid signal causes limiting to occur in the grid of V3 due to R4 in the grid circuit. Therefore, the negative-going portion is the only part of the input wave that has an appreciable effect on the plate current of V3. The positive pulse output is coupled to the grid of V4 through C4 and C5. C4 functions as an ordinary coupling capacitor; C5 in conjunction with R8 acts as a fast coupling network. The leading edge of the output pulse from V3 contains high frequency components. These are coupled through C5 which bypasses R8; therefore, the complete leading edge of the output of V3 is developed across R9. This sharp rise in voltage on the grid of V4 causes it to draw current charging the lower plate of C5 negatively, since C5 and R8 have RC time of approximately 1 second. The charge due to grid current rapidly discharges through R8 and returns the coupling circuit to a static condition.

If only C4 were used to couple the sharp rise to the grid of V4 when the grid drew current, the grid side of C4 would go negative. Since the discharge path for C4 is long, it would soon assume an average charge and the coupled signal would be reduced to minimum. The blocking oscillator V5 is normally cut off by a fixed negative voltage on the grid. This circuit is triggered by the output of V4 which is coupled to the grid. Positive range marks are taken from the cathode of V5.

MOVABLE RANGE MARKER

Many present day radarscopes utilize the movable marker or range strobe. This system provides a continuously variable marker that may be used to aid the operator in quickly determining the accurate range of a target. Movable marker action may be incorporated in a radar system by using multivibrators or the phantastron time delay circuits previously discussed in this chapter. Another system whereby such marker action amy be obtained is a timing circuit using a linear sawtooth and diode pickoff tube (fig. 14-19). This system is explained in detail in the following paragraphs.

The sweep generator tube V1, which is normally conducting, is cut off by the negative input square wave. When cut off, its plate voltage rises at a rate determined by the sweep capacitor C1. In order to obtain a linear sawtooth output it is necessary to use either the first ten percent of the charge or to add a bootstrap circuit to the sawtooth generator. This sawtooth waveform is applied to the plate of V2. V2 is normally cut off by the positive voltage on its cathode. The sawtooth rise applied to the plate of V2 eventually overcomes the cathode voltage and causes the diode to conduct. When this occurs the cathode voltage rises at the same rate as the plate voltage and is applied to the grid of V3. Tube V3, because of the transformer T1 in its plate circuit, then functions as a peaker amplifier. The output of V3 is applied to the grid of V4 and causes it to conduct momentarily. The current through the plate winding of T2, due to the conduction of V4, causes the single-swing blocking oscillator to cycle and produce the delayed pulse output.

The duration of the delay depends upon the voltage applied to the cathode of V2; this voltage is determined by the position of the potentiometer arm of R7. As the arm of the potentiometer is moved toward the more positive end, a higher voltage is then applied to the cathode of V2 and more time is required for V2 to start conducting, thus giving more delay before the pulse is produced. This delayed pulse is the movable marker that appears on the scope. Range is read from a mechanical counter or other indicating device which is mechanically coupled to the arm of the delay potentiometer R7. This counter is calibrated by adjusting the zero adjustment R10 and the slope adjustment R9. These potentiometers are positioned to provide the correct voltage across R7 so that the delay that is provided, dependent upon the location of its arm, is correctly indicated by the counter.

MOVABLE HEIGHT MARKER

The linear sawtooth delay circuit (fig. 14-19) may be used as the timing system for measuring target height with radar equipment. In order for it to apply to movable height markers, certain modifications must be made. The angle of elevation of the height finder antenna is referred to as ϕ. In the movable range

1053

CHAPTER 9

FEDERAL AIR REGULATIONS

Pilots of naval aircraft must comply with Federal Air Regulations. Although the AC is not directly concerned with the physical operation of an aircraft, he must, nonetheless, have a knowledge of the regulations which govern such operations. Based on this knowledge, the AC is able to issue instructions and information which allow pilots to operate aircraft in conformance with both the ATC instructions and the FAR's. Additionally, FAR's contain the general operating rules for holders of control tower operator certificates and ratings.

The study of this chapter is intended to provide the Air Controlman with a knowledge of air traffic rules and regulations. Only those parts, subparts, or certain paragraphs of FAR which the Air Controlman needs to know in his work are reprinted in this chapter. Additions, deletions, and explanations to FAR within the text have been made for clarification only.

This chapter is NOT intended to replace, substitute for, or supersede official regulations or directives which should be consulted for latest changes and final authority.

FAR, PART 1—DEFINITIONS AND ABBREVIATIONS

1.1 General definitions.

As used in this chapter—

"Administrator" means the Administrator of the Federal Aviation Administration or any person to whom he has delegated his authority in the matter concerned.

"Air Carrier" means a person who undertakes directly by lease, or other arrangement, to engage in air transportation.

"Air commerce" means interstate, overseas, or foreign air commerce or the transportation of mail by aircraft or any operation or navigation of aircraft within the limits of any Federal airway or any operation or navigation or aircraft which directly affects, or which may endanger safety in, interstate, overseas, or foreign air commerce.

"Aircraft" means a device that is used or intended to be used for flight in the air.

"Airplane" means an engine-driven fixed-wing aircraft heavier than air, that is supported in flight by the dynamic reaction of the air against its wings.

"Airport" means an area of land or water that is used or intended to be used for the landing and takeoff of aircraft, and includes its buildings and facilities, if any.

"Airport traffic area" means, unless otherwise specifically designated in Part 93 that airspace within a horizontal radius of 5 statute miles from the geographical center of any airport at which a control tower is operating, extending from the surface up to, but not including 2,000 feet above the surface.

"Airship" means an engine-driven lighter-than-air aircraft that can be steered.

"Air traffic" means aircraft operating in the air or on an airport surface, exclusive of loading ramps and parking areas.

"Air traffic clearance" means an authorization by air traffic control, for the purpose of preventing collision between known aircraft, for an aircraft to proceed under specified traffic conditions within controlled airspace.

"Air traffic control" means a service operated by appropriate authority to promote the safe, orderly, and expeditious flow of air traffic.

"Alternate airport" means an airport at which an aircraft may land if a landing at the intended airport becomes inadvisable.

"Approved," unless used with reference to another person, means approved by the Administrator.

"Armed Forces" means the Army, Navy, Air Force, Marine Corps, and Coast Guard, including their regular and reserve components

10560

and members serving without component status.

"Autorotation" means a rotorcraft flight condition in which the lifting rotor is driven entirely by action of the air when the rotorcraft is in motion.

"Balloon" means a ligher-than-air aircraft that is not engine driven.

"Calibrated airspeed" means indicated airspeed of an aircraft, corrected for position and instrument error. Calibrated airspeed is equal to true air speed in standard atmosphere at sea level.

"Ceiling" means the height above the earth's surface of the lowest layer of clouds or obscuring phenomena that is reported as "broken", "overcast," or "obscuration," and not classified as "thin" or "partial."

"Civil aircraft" means aircraft other than public aircraft.

"Controlled airspace" means airspace, designated as continental control area, control area, control zone, or transition area, within which some or all aircraft may be subject to air traffic control.

"Decision height" with respect to the operation of aircraft, means the height at which a decision must be made, during an ILS or PAR instrument approach, to either continue the approach or to execute a missed approach.

"Flight level" means a level of constant atmospheric pressure related to a reference datum of 29.92 inches of mercury. Each is stated in three digits that represent hundreds of feet. For example, flight level 250 represents a barometric altimeter indication of 25,000 feet; flight level 255, an indication of 25,500 feet.

"Flight plan" means specified information relating to the intended flight of an aircraft, that is filed orally or in writing with air traffic control.

"Flight visibility" means the average forward horizontal distance, from the cockpit of an aircraft in flight, at which prominent unlighted objects may be seen and identified by day and prominent lighted objects may be seen and identified by night.

"Foreign air carrier" means any person other than a citizen of the United States, who undertakes directly, by lease or other arrangement, to engage in air transportation.

"Glider" means a heavier-than-air aircraft, that is supported in flight by the dynamic reaction of the air against its lifting surfaces and whose free flight does not depend principally on an engine.

"Ground visibility" means prevailing horizontal visibility near the earth's surface as reported by the United States Weather Bureau or an accredited observer.

"Helicopter" means a rotorcraft that, for its horizontal motion, depends principally on its engine-driven rotors.

"Heliport" means an area of land, water, or structure used or intended to be used for the landing or takeoff of helicopters.

"IFR conditions" means weather conditions below the minimum for flight under visual flight rules.

"IFR over-the-top," with respect to the operation of aircraft, means the operation of an aircraft over-the-top on an IFR flight plan when cleared by air traffic control to maintain "VFR conditions" or "VFR conditions on top."

"Indicated airspeed" means the speed of an aircraft as shown on its pitot static airspeed indicator calibrated to reflect standard atmosphere adiabatic compressible flow at sea level uncorrected for airspeed system errors.

"Kite" means a framework, covered with paper, cloth, metal, or other material, intended to be flown at the end of a rope or cable, and having as its only support the force of the wind moving past its surfaces.

"Large aircraft" means aircraft of more than 12,500 pounds, maximum certificated takeoff weight.

"Lighter-than-air aircraft" means aircraft that can rise and remain suspended by using contained gas weighing less than the air that is displaced by the gas.

"Mach number" means the ratio of true airspeed to the speed of sound.

"Medical certificate" means acceptable evidence of physical fitness on a form prescribed by the Administrator.

"Minimum descent altitude" means the lowest altitude, expressed in feet above mean sea level, to which descent is authorized on final approach or during circle-to-land maneuvering in execution of a standard instrument approach procedure, where no electronic glide slope is provided.

"Navigable airspace" means airspace at and above the minimum flight altitudes prescribed by or under this chapter, including airspace needed for safe takeoff and landing.

"Night" means the time between the end of evening civil twilight and the beginning of

morning civil twilight, as published in the American Air Almanac, converted to local time.

"Non-precision approach procedure" means a standard instrument approach procedure in which no electronic glide slope provided.

"Operate," with respect to aircraft, means use, cause to use, or authorize to use aircraft for the purpose of air navigation, including the piloting of aircraft, with or without the right of legal control (as owner, lessee, etc.).

"Operational control," with respect to a flight, means the exercise of authority over initiating, conducting, or terminating a flight.

"Over-the-top" means above the layer of clouds or other obscuring phenomena forming the ceiling.

"Parachute" means a device used or intended to be used to retard the fall of a body or object through the air.

"Pilot in command" means the pilot responsible for the operation and safety of an aircraft during flight time.

"Positive control" means control of all air traffic, within designated airspace, by air traffic control.

"Precision approach procedure" means a standard instrument approach procedure in which an electronic glide slope is provided, as in ILS and PAR.

"Rating" means a statement that, as part of a certificate, sets forth special conditions, privileges, or limitations.

NOTE: Applies to FAA certificates only. Not to be confused with Navy enlisted rating.

"Prohibited area" means designated airspace within which the flight of aircraft is prohibited.

"Reporting point" means a geographical location in relation to which the position of an aircraft is reported.

"Restricted area" means airspace designated under Part 73 of this chapter within which the flight of aircraft, while not wholly prohibited, is subject to restriction.

"Rocket" means an aircraft propelled by ejected expanding gases generated in the engine from self-contained propellants and not dependent on the intake of outside substances. It includes any part which becomes separated during the operations.

"Rotorcraft" means a heavier-than-air aircraft that depends principally for its support in flight on the lift generated by one or more rotors.

"Route segment" means a part of a route. Each end of that part is identified by—

(1) a continental or insular geographical location; or

(2) a point at which a definite radio fix can be established.

"Small aircraft" means aircraft of 12,500 pounds or less, maximum certificated takeoff weight.

"True airspeed" means the airspeed of an aircraft relative to undisturbed air.

"Traffic pattern" means the traffic flow that is prescribed for aircraft landing at, taxiing on, or taking off from, an airport.

"United States," in a geographical sense, means (1) the States, the District of Columbia, Puerto Rico, and the possessions, including the territorial waters, and (2) the airspace of those areas.

"VFR over-the-top," with respect to the operation of aircraft, means the operation of an aircraft over-the-top under VFR when it is not being operated on an IFR flight plan.

1.2 Abbreviations and symbols.

In this chapter—

"ALS" means approach light system.

"ASR" means airport surveillance radar.

"ATC" means air traffic control.

"CAS" means calibrated airspeed.

"DH" means decision height.

"DME" means distance measuring equipment compatible with TACAN.

"FAA" means Federal Aviation Administration.

"FM" means fan marker.

"HIRL" means high-intensity runway lighting system.

"IAS" means indicated airspeed.

"ICAO" means International Civil Aviation Organization.

"IFR" means instrument flight rules.

"ILS" means instrument landing system.

"INT" means intersection.

"LMM" means compass locator at middle marker.

"LOM" means compass locator at outer marker.

"M" means Mach number.

"MAA" means maximum authorized IFR altitude.

"MALS" means medium intensity approach light system.

"MCA" means minimum crossing altitude.

10564

10564

"MDA" means minimum descent altitude.

"MEA" means minimum en route IFR altitude.

"MM" means ILS middle marker.

"MOCA" means minimum obstruction clearance altitude.

"MRA" means minimum reception altitude.

"MSL" means mean sea level.

"NDB(ADF)" means nondirectional beacon (automatic direction finding).

"NOPT" means no procedure turn required.

"PAR" means precision approach radar.

"RBN" means radio beacon.

"RCLM" means runway centerline marking.

"RCLS" means runway center line light system.

"REIL" means runway end identification lights.

"RVR" means runway visual range as measured in the touchdown area.

"SALS" means short approach light system.

"TACAN" means ultra-high frequency tactical air navigational aid.

"TAS" means true airspeed.

"TDZL" means touchdown zone lights.

"VFR" means visual flight rules.

"VHF" means very high frequency.

"VOR" means very high frequency omnirange station.

"VORTAC" means collocated VOR and TACAN.

1.3 Rules of construction.

(a) In this chapter, unless the context requires otherwise—

(1) Words importing the singular include the plural;

(2) Words importing the plural include the singular; and

(3) Words importing the masculine gender include the feminine:

(b) In this chapter the word—

(1) "Shall" is used in an imperative sense;

(2) "May" is used in a permissive sense to state authority or permission to do the act prescribed, and the words "no person may. . ." or "a person may not . . ." mean that no person is required, authorized, or permitted to do the act prescribed; and

(3) "Includes" means "includes but is not limited to."

FAR, PART 65—CERTIFICATION: AIRMEN OTHER THAN FLIGHT CREWMEMBERS

65.1 Applicability.

This part prescribes the requirements for issuing air traffic control tower operators certificates and associated ratings and the general operating rules for the holders of such certificates and ratings.

65.11 Application and issue.

(a) An application for a certificate and rating, or for an additional rating, under this Part is made on a form and in a manner prescribed by the Administrator.

(b) An applicant who meets the requirements of this Part is entitled to an appropriate certificate and rating.

(c) Unless authorized by the Administrator a person whose air traffic control tower operator certificate is suspeded may not apply for any rating to be added to that certificate during the period of suspension.

(d) Unless the order of revocation provides otherwise, a person whose air traffic control tower operator certificate is revoked may not apply for the same kind of certificate for one year after the date of revocation.

65.13 Temporary certificate.

A certificate and rating effective for a period of not more than 90 days may be issued to a qualified applicant, pending review of his application and supplementary documents and the issue of the certificate and ratings for which he applied.

65.15 Duration of certificates.

(a) An air traffic control tower operator certificate or rating issued under this Part is effective until it is surrendered, suspended, or revoked.

(b) The holder of any certificate issued under this Part that is suspended or revoked shall, upon the Administrator's request, return it to the Administrator.

65.16 Change of name; replacement of lost or destroyed certificate.

(a) An application for a change of name on a certificate issued under this Part must be

10563

accompanied by the applicant's current certificate and the marriage license, court order, or other document verifying the change. The documents are returned to the applicant after inspection.

(b) An application for a replacement of a lost or destroyed certifice is made by letter to the FAA Airman Certification Branch, Federal Aviation Administration, Oklahoma City, Oklahoma. The letter must:

(1) Contain any available information regarding the grade, number and date of issue of the certificate, the name in which it was issued, and the ratings on it; and

(2) Be accompanied by a check or money order for $2.00, payable to the FAA.

(c) An application for replacement of a lost or destroyed medical certifice is made by letter to the Aeromedical Certification Branch, Civil Aeromedical Institute, FAA, P.O. Box 1082, Oklahoma City, Oklahoma 73101, accompanied by a check or money order for $2.00.

(d) A person whose certificate issued under this Part or medical certificate, or both, has been lost may obtain a telegram from the FAA confirming that it was issued. The telegram may be carried as a certificate pending his receiving a duplicate certificate under paragraph (b) or (c) of this section, unless he has been notified that the certificate has been suspended or revoked. The request for such a telegram may be made by prepaid telegram, stating the date upon which a duplicate certificate was requested, or including the request for a duplicate and a money order for the necessary amount. The request for a telegraphic certificate should be sent to the office prescribed in paragraph (b) or (c) of this section, as appropriate. However, a request for both at the same time should be sent to the office prescribed in paragraph (b) of this section.

65.17 Tests: general procedure.

(a) Tests prescribed by or under this Part are given at times and places, and by persons, designated by the Administrator.

(b) The minimum passing grade for each test is 70 percent.

65.18 Written tests: cheating or other unauthorized conduct.

(a) Except as authorized by the Administrator, no person may:

(1) Copy, or intentionally remove, a written test under this Part;

(2) Give to another, or receive from another, any part or copy of that test;

(3) Give help on that test to, or receive help on that test from, any person during the period that test is being given;

(4) Take any part of that test in behalf of another person;

(5) Use any material or aid during the period that tests are being given, or;

(6) Intentionally cause, assist, or participate in any act prohibited by this paragraph.

(b) No person who commits an act prohibited by paragraph (a) of this section is eligible for any certificate or rating under this chapter for a period of one year after the date of that act. In addition, the commission of that act is a basis for suspending or revoking any certificate or rating held by that person.

65.19 Retesting after failure.

An applicant who fails a written, oral, or practical test for a certificate and rating, or for an additional rating, under this Part may apply for retesting—

(a) After 30 days after the date he failed the test; or

(b) Upon presenting a statement from a certificated and appropriately rated ground instructor or air traffic control tower operator, certifying that he has given the applicant at least 5 hours of additional instruction in each of the subjects failed and now consideres that the applicant is ready for retesting for the air traffic control tower operator certificate.

65.20 Fraudulent or false statements or records.

(a) No person may make or cause to be made:

(1) Any fraudulent or intentionally false statement on any application for a certificate or rating under this Part;

(2) Any reproduction, for fraudulent purpose, of any certificate or rating under this Part; or

(3) Any alteration of any certificate or rating under this Part.

(b) The commission by any person of an act prohibited under paragraph (a) of this section is a basis for suspending or revoking any certificate or rating held by that person.

10564

65.21 Change of address.

Within 30 days after any change in his permanent mailing address, the holder of a certificate issued under this Part shall notify the FAA Airman Certification Branch, Oklahoma City, Oklahoma, in writing, of his new address.

65.30 Certificate and rating required.

No person may act as an air traffic control tower operator in connection with any civil aircraft in air commerce unless he holds an air traffic control tower operator certificate and an appropriate rating issued to him under this part. NOTE: OpNav Instruction 3722.6 (Series) promulgates the applicability of these regulations to Navy AC's.

65.31 Eligibility requirements: general.

To be eligible for an air traffic control tower operator certificate, a person must—

(a) Be at least 21 years of age;

(b) Be of good moral character;

(c) Be able to read, write, and understand the English language and speak it without accent or impediment of speech that would interfere with two-way radio conversations;

(d) Hold at least a second-class medical certificate issued under FAR, Part 67 within the 12 months before the date he applies; and

(e) Comply with 65.33.

A certificate that is held by a member of an Armed Force who is less than 21 years of age is valid only while he is serving as a member in a control tower operated by an Armed Force.

65.33 Knowledge requirements.

Each applicant for a certificate must pass a written test on the following:

(a) The flight rules in Part 91 of this chapter.

(b) Airport traffic control procedures, and this subpart.

(c) En route traffic control procedures.

(d) Communications operating procedures.

(e) Flight assistance service.

(f) Air navigation and aids to air navigation.

(g) Aviation weather.

65.35 Ratings.

The holder of an air traffic control tower operator certificate is entitled to a junior or senior rating, based on his qualifications to perform the duties of an operator at a particular airport.

65.37 Skill requirements: junior rating.

For a junior rating, an air traffic control tower operator must pass a practical test on—

(a) The control tower, including equipment, its use, and hazards to operations;

(b) The airport, including rules, facilities and their use, and hazards to operations;

(c) The control zone, including prominent objects, reporting points, traffic patterns, and hazards to operations;

(d) Notices to Airmen;

(e) Weather facilities and procedures, including weather stations, sequence reports, forecasts, and visibility check points; and

(f) Controlling air traffic under VFR conditions.

65.39 Skill requirements: senior rating.

(a) For a senior rating, an air traffic control tower operator must pass the test for a junior rating, meet the requirements of paragraphs (b) and (c) of this section, and pass a practical test on—

(1) The tower, the center, and the airways serving the airport;

(2) Air navigation facilities, including beacons, ranges, fan markers, compass locators, and instrument landing systems and ground controlled approach if these procedures or facilities have been established;

(3) Using the Airman's Information Manual;

(4) (Number reserved for future use);

(5) Holding procedures;

(6) The standard instrument approach procedures and tower approach control procedures, if approach control has been established;

(7) Missed approaches;

(8) Alternate airports;

(9) Search and rescue procedures; and

(10) Controlling air traffic under IFR conditions.

(b) An applicant for a senior rating must have satisfactorily served—

(1) As an operator with a senior rating for at least 6 months;

(2) As an operator with a junior rating, for at least the 6 months before the date he applies for rating, at the airport for which he seeks a rating;

(3) As an air traffic control trainee for at least 6 months in the service of the United States, or

(4) As an operator with a junior rating, at an airport other than the one for which he seeks a rating or as an operator at a landing area under the jurisdication of an Armed Force of the United States, for at least 1 of the 2 years before the date he applies for the rating.

(c) An applicant for a senior rating must show that he can satisfactorily supervise and manage all activities of the airport control tower, including preparing such reports as may be required by the airport manager or the Administrator.

65.41 Performance of duties.

(a) An air traffic control tower operator shall perform his duties in accordance with the limitations on his certificate and rating and the procedure and practices prescribed in air traffic control manuals of the FAA, to provide for the safe, orderly, and expeditious flow of air traffic.

(b) Whenever weather conditions are at least as good as the basic minimums prescribed for VFR flight by Part 91 of this chapter, an operator with either a senior or junior rating may control air traffic at the airport concerned. However, if the character or volume of the air traffic, the type and equipment of aircraft using the airport, or the airport facilities, require that an operator with a junior rating be supervised, an operator with a senior rating shall supervise the controlling of all air traffic at the airport.

(c) Whenever weather conditions are below the basic minimums prescribed for VFR flight by Part 91 of this chapter an operator with a senior rating shall supervise the controlling of all air traffic at the airport concerned. However, he may not issue an air traffic clearance for flight without advance authority from the appropriate air route traffice control center.

(d) In an emergency, an operator with a senior rating may delegate his authority to an operator with a junior rating.

65.43 Maximum hours.

Except in an emergency, a certificated air traffic control tower operator must be relieved of all duties for at least 24 consecutive hours at least once during each 7 consecutive days. Such an operator may not serve or be required to serve—

(a) For more than 10 consecutive hours; or

(b) For more than 10 hours during a period of 24 consecutive hours, unless he has a rest period of at least 8 hours at or before the end of the 10 hours of duty.

65.45 General operating rules.

(a) Each person who holds an air traffic control tower operator certificate shall keep it readily available when performing duties under it, and shall present that certificate or a medical certificate held by him, or both, for inspection upon request of the Administrator or an authorized representative of the National Transportation Safety Board, or of any Federal, State, or local law enforcement office.

(b) No person may act as an air traffic control tower operator under a certificate issued to him under this Part unless he has in his personal possession an appropriate current medical certificate issued under FAR, Part 67.

(c) An air traffic control tower operator may not perform duties under his certificate during any period of known physical deficiency that would make him unable to meet the physical requirements for his current medical certificate. However, if the deficiency is temporary, he may perform duties that are affected by it when ever another certificated and qualified operator is present and on duty.

(d) A certificated air traffic control tower operator may not control air traffic with facilities that the Administrator has found to be inadequate.

(e) The holder of an air traffic control tower operator certificate or an applicant for one, shall, upon the reasonable request of the Administrator, cooperate fully in any test that is made of him.

10566

65.47 Recent experience.

The holder of an air traffic control tower operator certificate may not perform any duties under that certificate unless—

(a) In the case of a junior operator, he has served for at least 3 of the preceding 12 months as an operator at the airport to which his rating applies;

(b) In the case of a senior operator, he has served for at least 3 of the preceding 6 months as an operator at the airport to which his rating applies; or

(c) He has shown to the satisfaction of the Administrator that he meets the standards for his certificate and rating.

FAR, PART 67—MEDICAL STANDARDS AND CERTIFICATION

67.1 Applicability.

This Part prescribes the medical standards for issuing medical certification for airmen.

67.11 Issue.

An applicant who meets the medical standards of this Part, based on medical examination and evaluation of his history and condition, is entitled to an appropriate medical certificate.

Medical certificates are designated as First, Second, and Third Class, with established medical standards for each class.

Air Controlmen are required to possess a Second Class medical certificate.

Medical examinations are given by an examiner designated by the FAA. The FAA has designated flight surgeons of the Armed Forces on specified military posts, stations, and facilities to give physical examinations to applicants for FAA medical certificates who are on active duty, or who are, under Department of Defense medical programs, eligible for FAA medical certification as civil airmen. In addition, such examiners may issue or deny, as appropriate, FAA medical certificates in accordance with the regulations of Part 67 and policies of the FAA

FAR, PART 71—DESIGNATION OF FEDERAL AIRWAYS, CONTROLLED AIRSPACE, AND REPORTING POINTS

71.3 Classification of Federal airways.

Federal airways are classified as follows:
(a) Colored Federal airways -

(1) Green Federal airways.
(2) Amber Federal Airways.
(3) Red Federal airways.
(4) Blue Federal airways.

(b) VOR Federal airways.

71.5 Extent of Federal airways.

(a) Each Federal airway is based on a centerline that extends from one navigation aid or intersection to another navigation aid (or through several navigation aids or intersections) specified for that airway.

(b) Unless otherwise specified—(1) Each Federal airway includes the airspace within parallel boundary lines 4 nautical miles each side of the center line. Where an airway changes direction, it includes the airspace that is enclosed by extending the boundary lines of the airway segments until they meet.

(c) Unless otherwise specified—

(1) Each Federal airway includes the airspace that extends upward from 1,200 feet above the surface of the earth to, but not including, 18,000 feet MSL, except that Federal airways for Hawaii have no upper limits. Variations of the lower limits of an airway are expressed in hundreds of feet above the surface (AGL) or mean sea level (MSL) and, unless otherwise specified, apply to the segment of an airway between adjoining navigational aids or intersections.

(2) The airspace of a Federal airway within the lateral limits of a transition area has a floor coincident with that of the transition area.

(d) One or more alternate airways may be designated between specified navigational aids or intersections along each VOR Federal airway. Unless otherwise specified, the centerline of an alternate VOR Federal airway and the centerline of the main VOR Federal airway are separated by 15°.

(e) A Federal airway does not include the airspace of a prohibited area.

71.7 Control areas.

Control areas consist of Federal airways, additional control areas, and control area extensions, but do not include the continental control area. Unless otherwise designated, control areas include the airspace between a segment of a main VOR Federal airway and its associated alternate segments with the vertical extent of the area corresponding to the vertical extent of the related segment of the airway.

71.9 Continental control area.

The continental control area consists of the airspace of the 48 contiguous states, the District of Columbia, and Alaska south of latitude 68 degrees north, excluding the Alaska peninsula west of longitude 160 degrees west, at and above 14,500 feet, but does not include—

(a) The airspace less than 1,500 feet above the surface of the earth; or

(b) Prohibited and restricted areas, other than restricted area military climb corridors and the restricted areas listed in 71.151. Part 71.151 is not printed in this training manual.

71.11 Control zones.

Control zones consist of controlled airspace which extends upwards from the surface of the earth and terminates at the base of the continental control area. Control zones that do not underlie the continental control area have no upper limit. A control zone is normally a circular area with a radius of 5 miles and any extensions necessary to include instrument approach and departure paths.

71.13 Transition areas.

Transition areas consist of controlled airspace extending upward from 700 feet or more above the surface of the earth when designated in conjunction with an airport for which an approved instrument approach procedure has been prescribed; or from 1,200 feet or more above the surface of the earth when designated in conjunction with airway route structures or segments. Unless otherwise spedified, transition areas terminate at the base of the overlying controlled airspace.

71.15 Positive control areas.

Positive control areas consist of controlled airspace within which there is positive control or aircraft.

71.17 Reporting points.

(a) Reporting points consists of geographic locations, in relation to which the position of an aircraft must be reported in accordance with 91.125.

(b) Unless otherwise designated, each reporting point applies to all directions of flight. In any case where a geographic location is designated as a reporting point for one or more airways, or for a particular direction of flight along an airway only, it is so indicated by including the airways or direction of flight in the designation of geographical location.

(c) Unless otherwise specified, place names appearing in the reporting point descriptions indicate VOR or VORTAC facilities identified by those names.

71.163 Designation of additional control areas.

Unless otherwise specified, each additional control area designated as other than previously described has a lateral extent identical to that of a Federal airway and extends upward from 700 feet (until designated from 1,200 feet or more) above the surface of the earth. An exception is that the airspace of a control area within the lateral limits of a transition area has a floor coincident with the floor of the transition area.

71.165 Designation of control area extensions.

Unless otherwise specified, each designated control area extension extends upward from 700 feet above the surface of the earth, except that the airspace of a control area extension within the lateral limits of a transition area has a floor coincident with that of the transition area.

10368

Figure 14-19. —Sawtooth type movable marker.

marker (fig. 14-19), a fixed supply potential was used for the sawtooth generator, but when this circuit is used for height finding the supply voltage varies with the angle of elevation of the antenna. Thus, the slope of the sawtooth is proportional to sin ϕ. In this application the counter or other indicator that is connected to the delay potentiometer indicates the target's height.

The curvature of the earth may be neglected when determining height at short or medium ranges. The relationship between delay time and target height, or the time when the height marker appears on the sweep, may be expressed as follows:

$$T = \frac{2H}{C \sin \phi}$$

T equals time
H equals height
C equals speed of radio waves
ϕ equals angle of elevation

Since the slope of the sawtooth has been made proportional to sin ϕ, the time delay is inversely proportional to sin ϕ or, in other words, directly proportional to

$$\frac{1}{\sin \phi}$$

for a given diode bias.

1054 6801

75.11 Jet routes.

Each jet route consists of a direct course for navigating aircraft between 18,000 feet MSL and flight level 450, inclusive, between the navigational aids and intersections specified for that route.

75.15 Jet advisory areas.

(a) Jet advisory areas consist of airspace as designated, within the continental control area.

(b) En route radar jet advisory areas consist of areas within which jet advisory service is provided by using radar. Unless otherwise designated, each of them includes the area within 14 miles on each side of the jet route segment from flight level 240 through flight level 410, inclusive.

(c) Terminal radar jet advisory areas consist of areas in which jet advisory service is provided by using radar. Unless otherwise designated, each of them includes the area within 14 miles on each side of the VOR/VORTAC radials, bearings from L/MF navigational facilities, direct courses between navigational facilities, or centerlines of control areas from flight level 240 through flight level 410, inclusive.

(d) Nonradar jet advisory areas consist of areas within which jet advisory service is provided on a procedural basis without the use of radar. Unless otherwise designated, each of them includes the area within 14 miles on each side of the jet route segment from flight level 270 through flight level 310, inclusive, and from flight level 370 through flight level 410, inclusive.

(e) Jet advisory areas do not include the airspace within positive control areas, prohibited areas, or restricted areas except restricted area military climb corridors and other restricted areas so specified.

(f) Jet advisory areas that are based on jet routes are identified by the associated jet route number. Those based on VOR/VORTAC radials, bearings from L/MF navigational facilities, direct courses between navigational facilities, or centerlines of control areas and those in the vicinity of geographical locations, are identified by geographical names.

FAR, PART 91—GENERAL OPERATING AND FLIGHT RULES

Subpart A—General

91.1 Applicability.

(a) Except as provided in paragraph (b) of this section, this Part prescribes rules governing the operation of aircraft (other than moored balloons, kites, unmanned rockets, and unmanned free balloons) within the United States.

(b) Each person operating an aircraft of U.S. registry in air commerce over the high seas shall comply with Annex 2 (Rules of the Air) to the convention on International Civil Aviation.

91.3 Responsibility and authority of the pilot in command.

(a) The pilot in command of an aircraft is directly responsible for, and is the final authority as to, the operation of that aircraft.

(b) In an emergency requiring immediate action, the pilot in command may deviate from any rule of this subpart or of Subpart B to the extent required to meet that emergency.

(c) Each pilot in command who deviates from a rule under paragraph (b) of this section shall, upon the request of the Administrator, send a written report of that deviation to the Administrator.

91.5 Preflight action.

Each pilot in command shall, before beginning a flight, familiarize himself with all available information concerning that flight. This information must include, for a flight under IFR or a flight not in the vicinity of an airport, available weather reports and forecasts, fuel requirements, alternatives available if the planned flight cannot be completed, and any known traffic delays of which he has been advised by ATC.

91.7 Flight crewmembers at stations.

During takeoff and landing, and while en route, each required flight crewmember shall—

(a) Be at his station unless his absence is necessary in the performance of his duties in connection with the operation of the aircraft

or in connection with his physiological needs; and

(b) Keep his seat belt fastened while at his station.

91.8 Prohibition against interference with crewmembers.

(a) No person may assault, threaten, intimidate, or interfere with a crewmember in the performance of his duties aboard an aircraft being operated in air commerce.

(b) No person may attempt to cause or cause the flight crew of an aircraft being operated in air commerce to divert its flight from its intended course or destination.

91.9 Careless or reckless operation.

No person may operate an aircraft in a careless or reckless manner so as to endanger the life or property of another.

91.10 Careless or reckless operation other than for the purpose of air navigation

No person may operate an aircraft, other than for the purpose of air navigation, on any part of the surface of an airport used by aircraft for air commerce (including areas used by those aircraft for receiving or discharging persons or cargo), in a careless or reckless manner so as to endanger the life or property of another.

91.11 Liquor and drugs.

(a) No person may act as a crewmember of a civil aircraft while—

(1) Under the influence of intoxicating liquor; or

(2) Using any drug that affects his faculties in any way contrary to safety.

(b) Except in an emergency, no pilot of a civil aircraft may allow a person who is obviously under the influence of intoxicating liquors or drugs (except a medical patient under proper care) to be carried in that aircraft.

91.13 Dropping objects.

No pilot in command of a civil aircraft may allow any object to be dropped from that aircraft in flight that creates a hazard to persons or property. However, this section does not prohibit the dropping of any object if reasonable precautions are taken to avoid injury or damage to persons or property.

91.15 Parachutes and parachuting.

(a) No pilot of a civil aircraft may allow a parachute that is available for emergency use to be carried in the aircraft unless it is an approved type and—

(1) If a chair type (canopy in back), it has been packed by an appropriately rated parachute rigger within the preceding 120 days; or

(2) If any other type, it has been packed by an appropriately rated parachute rigger within the preceding 60 days.

(b) Except in an emergency, no pilot in command may allow, and no person may make, a parachute jump from an aircraft, within the U.S., except in accordance with Part 105.

91.18 Towing.

(a) No pilot of a civil aircraft may tow anything with that aircraft (other than gliders) except in accordance with the terms of a certificate of waiver issued by the Administrator. Rules and regulations for glider towing operations, without the necessity of obtaining a waiver, are covered in FAR 91.17 but are not included in this training manual. For glider towing operations other than those authorized under 91.17, a certificate of waiver is not issued to tow a glider unless the pilot is qualified under FAR Part 61.

(b) An application for a certificate of waiver under this section is made on a form and in a manner prescribed by the Administrator and must be submitted to the nearest Flight Standards District Office.

91.19 Portable electronic devices.

Except as provided in the following paragraphs of this section, no person may operate, nor may any operator or pilot in command of an aircraft allow the operation of any portable electronic device on any of the following U.S. registered civil aircraft:

1. Aircraft operated by an air carrier or commercial operator; or

2. Any other aircraft while it is operating under IFR.

The preceding paragraph does not apply to:

a. Portable voice recorders.

10571

b. Hearing aids.
c. Heart pacemakers.
d. Electric shavers.
e. Any other portable electronic device that an aircarrier, commercial operator, pilot in command, or other operator of aircraft has determined will not cause interference with the navigation or communication system of the aircraft on which it is to be used.

91.21 Flight instruction and simulated instrument flight.

(a) No person may operate a civil aircraft that is being used for flight instruction unless that aircraft has fully functioning dual controls.

(b) No person may operate a civil aircraft in simultated instrument flight unless—

(1) An appropriately rated pilot occupies the other control set as a safety pilot;

(2) The safety pilot has adequate vision forward and to each side of the aircraft, or a competent observer adequately supplements the vision of the safety pilot; and

(3) Except in the case of a lighter-than-air aircraft, that aircraft is equipped with functioning dual controls.

91.23 Fuel requirements for flight in IFR conditions.

No person may operate a civil aircraft in IFR conditions unless it carrier enough fuel (considering weather reports and forecasts, and weather conditions) to—

(a) Complete the flight to the first airport of intended landing;

(b) Fly from the airport to the alternate airport; and

(c) Fly thereafter for 45 minutes at normal cruising speeds.

However, the requirements for fuel to fly from the first airport of intended landing to the alternate airport does not apply if an approved instrument approach procedure has been established for the first airport of intended landing and the weather conditions at that airport are forecast to be, from 2 hours before to 2 hours after the estimated time of arrival, a ceiling of at least 1,000 feet above the lowest MEA, MOCA, or altitude prescribed for the initial approach segment of the instrument approach procedure for the airport and visibility at least 3 miles, or 2 miles more than the lowest authorized landing minimum visibility, whichever is greater.

Subpart B—Flight Rules.

91.61 Applicability.

This subpart prescribes flight rules governing the operation of aircraft within the United States.

91.63 Waivers.

(a) The Administrator may issue a certificate of waiver authorizing the operation of aircraft in deviation of any rule of this subpart if he finds that the purposed operation can be safely conducted under the terms of that certificate of waiver.

(b) An application for a certificate of waiver under this section is made on a form and in a manner prescribed by the Administrator and may be submitted to any FAA office.

(c) A certificate of waiver is effective as specified in that certificate.

91.65 Operating near other aircraft.

(a) No person may operate an aircraft so close to another aircraft as to create a collision hazard.

(b) No person may operate an aircraft in formation flight except by arrangement with the pilot in command of each aircraft in the formation.

(c) No person may operate an aircraft, carrying passengers for hire, in formation flight.

(d) Unless otherwise authorized by ATC, no person operating an aircraft may operate his aircraft in accordance with any clearance or instruction that has been issued to the pilot of another aircraft for radar air traffic control purposes.

91.67 Right-of-way rules; except water operations.

(a) General. When weather conditions permit, regardless of whether an operation is conducted under IFR or VFR, vigilance shall be maintained by each person operating an aircraft so as to see and avoid other aircraft in compliance with this section. When a rule of this section gives another aircraft the right of way, he shall give way to that aircraft and may not pass over, under, or ahead of it, unless well clear.

10572

(b) In distress. An aircraft in distress has the right of way over all other air traffic.

(c) Converging. When aircraft of the same category are converging at approximately the same altitude (except head-on, or nearly so) the aircraft to the other's right has the right of way. (See fig. 9-1.) If the aircraft are of different categories—

(1) A balloon has the right of way over any other category of aircraft;

(2) A glider has the right of way over an airship, airplane or rotorcraft; and

(3) An airship has the right of way over an airplane or rotorcraft.

However, an aircraft towing or refueling other aircraft has the right of way over all other engine-driven aircraft.

(d) Approaching head-on. When aircraft are approaching each other head-on, or nearly so, each pilot of each aircraft shall alter course to the right. (See fig. 9-2.)

(e) Overtaking. Each aircraft that is being overtaken has the right of way and each pilot of an overtaking aircraft shall alter course to the right to pass well clear. (See fig. 9-3.)

AC.121

Figure 9-1.—Converging aircraft.

AC.122

Figure 9-2.—Aircraft approaching head-on.

NOTE: Passing an overtaken aircraft on the right is required because the pilot in side-by-side, dual-control aircraft is seated on the left and has a better view on that side. Further, in narrow traffic lanes, passing on the left of an overtaken aircraft would place the overtaking aircraft in the path of oncoming traffic.

10573
10235

AC.123

Figure 9-3.—Aircraft overtaking another.

(f) Landing. Aircraft, while on final approach to land, or while landing, have the right of way over other aircraft in flight or operating on the surface. When two or more aircraft are approaching an airport for the purpose of landing, the aircraft at the lower altitude has the right of way, but it shall not take advantage of this rule to cut in front of another which is on final approach to land, or to overtake that aircraft.

(g) Inapplicability. This section does not apply to the operation of an aircraft on water.

91.69 Right-of-way rules; water operations.

(a) General. Each person operating an air craft on the water shall, insofar as possible, keep clear of all vessels and avoid impeding their navigation, and shall give way to any vessel or other aircraft that is given the right of way by any rule of this section.

(b) Crossing. When aircraft, or an aircraft and a vessel are on crossing courses, the aircraft or vessel to the other's right has the right of way.

(c) Approaching head-on. When aircraft, or an aircraft and a vessel, are approaching head-on or nearly so, each shall alter its course to the right to keep well clear.

(d) Overtaking. Each aircraft or vessel that is being overtaken has the right of way, and the one overtaking shall alter course to keep well clear.

(e) Special circumstances. When aircraft, or an aircraft and a vessel, approach so as to involve risk of collision, each aircraft or vessel shall proceed with careful regard to existing circumstances, including the limitations of the respective craft.

91.70 Aircraft speed.

(a) Unless otherwise authorized by the Administrator, no person may operate an aircraft below 10,000 feet MSL at an indicated airspeed of more than 250 knots.

(b) Unless otherwise authorized or required by ATC, no person may operate an aircraft within an airport traffic area at an indicated airspeed of more than—

(1) In the case of reciprocating engine aircraft, 156 knots; or

(2) In the case of turbine-powered aircraft, 200 knots.

However, if the minimum safe airspeed for any particular operation is greater than the maximum speed prescribed in this section, the aircraft may be operated at that minimum speed.

91.71 Acrobatic flight.

(a) No person may operate an aircraft in acrobatic flight—

(1) Over any congested area of a city, town, or settlement;

(2) Over an open air assembly of persons;

(3) Within a control zone or Federal airway;

(4) Below an altitude of 1,500 feet above the surface; or

(5) When flight visibility is less than three miles.

10574

For the purpose of this paragraph, acrobatic flight means an intentional maneuver involving an abrupt change in an aircraft's attitude, an abnormal attitude, or abnormal acceleration, not necessary for normal flight.

(b) Unless each occupant of the aircraft is wearing an approved parachute, no pilot of a civil aircraft, carrying any person (other than a crewmember) may execute any intentional maneuver that exceeds—

(1) A bank of 60 degrees relative to the horizon; or

(2) A nose up or nose down attitude of 30 degrees relative to the horizon.

(c) Paragraph (b) of this section does not apply to—

(1) Flight tests for pilot certification or rating; or

(2) Spins and other flight maneuvers required by the regulations for any certificate or rating when given by a certified flight instructor, or an airline transport pilot instructing in accordance with FAR 61.

91.73 Aircraft lights.

No person may, during the period from sunset to sunrise (or, in Alaska, during the period a prominent unlighted object cannot be seen from a distance of three statute miles or the sun is more than six degrees below the horizon)—

(a) Operate an aircraft unless it has lighted position lights;

(b) Park or move an aircraft in, or in dangerous proximity to, a night flight operations area of an airport unless the aircraft—

(1) Is clearly illuminated;

(2) Has lighted position lights; or

(3) Is in an area which is marked by obstruction lights; or

(c) Anchor an aircraft unless the aircraft—

(1) Has lighted anchor lights; or

(2) Is in an area where anchor lights are not required on vessels.

91.75 Compliance with ATC clearances and instructions.

(a) When an ATC clearance has been obtained, no pilot in command may deviate from that clearance, except in an emergency, unless he obtains an amended clearance. However, except in positive controlled airspace, this paragraph does not prohibit him from cancelling an IFR flight plan if he is operating in VFR weather conditions.

(b) Except in an emergency, no person may, in an area in which air traffic control is exercised, operate an aircraft contrary to an ATC instruction.

(c) Each pilot in command who deviates, in an emergency, from an ATC clearance or instruction shall notify ATC of that deviation as soon as possible.

(d) Each pilot in command who (though not deviating from a rule of this subpart) is given priority by ATC in an emergency, shall, if requested by ATC, submit to the chief of that ATC facility a detailed report of that emergency within 48 hours.

91.79 Minimum safe altitudes; general.

Except when necessary for takeoff or landing, no person may operate an aircraft below the following altitudes:

(a) Anywhere. An altitude allowing, if a power unit fails, an emergency landing without undue hazard to persons or property on the surface. (See fig. 9-4.)

(b) Over congested areas. Over any congested area of a city, town, or settlement, or over any open air assembly of persons, an altitude of 1,000 feet above the highest obstacle within a horizontal radius of 2,000 feet of the aircraft. (See fig. 9-5.)

(c) Over other than congested areas. An altitude of 500 feet above the surface, except over open water or sparsely populated areas. In that case the aircraft may not be operated closer than 500 feet to any person, vessel, vehicle, or structure. (See fig. 9-6.)

(d) Helicopters. Helicopters may be operated at less than the minimums prescribed in paragraphs (b) or (c) of this section if the operation is conducted without hazard to persons or property on the surface. In addition, each person operating a helicopter shall comply with routes or altitudes specifically prescribed for helicopters by the Administrator.

91.81 Altimeter settings.

(a) Each person operating an aircraft shall maintain that aircraft's cruising altitude or

10575

AC.124

Figure 9-4.—Minimum safe altitudes—anywhere.

flight level, as the case may be, by reference to an altimeter that is set, when operating—

(1) Below 18,000 feet MSL, to—

(i) The current reported altimeter setting of a station along the route and within 100 nautical miles of the aircraft;

(ii) If there is no station within the area prescribed in subdivision (i) of this subparagraph, the current reported altimeter setting of an appropriate available station; or

(iii) In the case of an aircraft not equipped with a radio, the elevation of the departure airport or an appropriate altimeter setting available before departure; or

(2) At or above 18,000 feet MSL, to 29.92" Hg.

(b) The lowest usable flight level is determined by the atmospheric pressure in the area of operation, as shown in the following listing:

Altimeter setting (Current reported)	Lowest usable flight level
29.92 or higher	180
29.91 to 29.42	185
29.41 to 28.92	190
28.91 to 28.42	195
28.41 to 27.92	200
27.91 to 27.42	205
27.41 to 26.92	210

(c) To convert minimum safe altitude to minimum flight level, the pilot should add the appropriate number of feet specified below, according to the current altimeter setting, to the flight level equivalent of the minimum safe altitude.

29.92 (or higher)	None
29.91 to 29.42	500 feet
29.41 to 28.92	1,000 feet
28.91 to 28.42	1,500 feet
28.41 to 27.92	2,000 feet
27.91 to 27.42	2,500 feet
27.41 to 26.92	3,000 feet

TT3010576

AC.125

Figure 9-5.—Minimum safe altitude over congested areas.

AC.126

Figure 9-6.—Minimum safe altitude over other than congested areas.

91.83 Flight plan; information required.

(a) Unless otherwise authorized by ATC, each person filing an IFR or VFR flight plan shall include in it the following information:

(1) The aircraft identification number and, if necessary, its radio call sign.

(2) The type of the aircraft or, in the case of a formation flight, the type of each aircraft and the number of aircraft, in the formation.

(3) The full name and address of the pilot in command or, in the case of a formation flight, the formation commander.

(4) The point and proposed time of departure.

(5) The proposed route, cruising altitude (or flight level), and true airspeed at that altitude.

(6) The point of first intended landing and the estimated elapsed time until over that point.

(7) The radio frequencies to be used.

(8) The amount of fuel on board (in hours).

(9) In the case of an IFR flight plan, an alternate airport, except as provided in paragraph (b) of this section.

(10) In the case of an international flight, the number of persons in the aircraft.

(11) Any other information the pilot in command or ATC believes necessary for ATC purposes.

When a flight plan has been filed, the pilot in command, upon canceling or completing the flight under the flight plan, shall notify the nearest FAA Flight Service Station or ATC facility.

(b) Paragraph (a) (9) of this section does not apply if FAR Part 97 prescribes a standard instrument approach procedure for the first airport of intended landing and the weather conditions at that airport are forecast to be, from two hours before to two hours after the ETA, as follows:

(1) A ceiling of at least 1,000 feet above the lowest MEA, MOCA, or altitude prescribed for the initial approach segment of the instrument approach procedure for the airport.

(2) Visibility at least 3 miles, or 2 miles more than the lowest authorized landing minimum visibility, whichever is greater.

(c) IFR alternate airport weather minimums. Unless otherwise authorized by the Administrator, no person may include an alternate airport in an IFR flight plan unless current weather forecasts indicate that, at the ETA at the alternate airport, the ceiling and visibility at that airport will be at or above the following alternate airport weather minimums:

(1) If an instrument approach procedure has been published in FAR Part 97 for that airport, the alternate airport minimums specified in that procedure or, if none are so specified, the following minimums:

(i) Precision approach procedure: ceiling 600 feet and visibility 2 statute miles.

(ii) Non-precision approach procedure: ceiling 800 feet and visibility 2 statute miles.

(iii) If no instrument approach procedure has been published in FAR Part 97 for that airport, the ceiling and visibility minimums are those allowing descent from the MEA, approach, and landing, under basic VFR.

91.85 Operating on or in the vicinity of an airport; general rules.

(a) Unless otherwise required by Part 93 (Special air traffic rules and airport traffic patterns) each person operating an aircraft on or in the vicinity of an airport shall comply with the requirements of this section and of 91.87 and 91.89.

(b) Unless otherwise authorized or required by ATC, no person may operate an aircraft within an airport traffic area except for the purpose of landing at, or taking off from, an airport within that area. ATC authorizations may be given as individual approval of specific operations or may be contained in written agreements between airport users and the tower concerned.

91.87 Operation at airports with operating control towers.

(a) General. Unless otherwise authorized or required by ATC, each person operating an aircraft to, from, or on an airport with an operating control tower shall comply with the applicable provisions of this section.

(b) Communications with control towers operated by the United States. No person may, within an airport traffic area, operate an aircraft to, from, or on an airport having a control tower operated by the United States unless two-way radio communications are maintained between that aircraft and the control tower. However, if the aircraft radio fails in flight, he may operate that aircraft and land if weather conditions are at or above basic VFR weather

10578

minimums, he maintains visual contact with the tower, and he receives a clearance to land. If the aircraft radio fails while in flight under IFR, he must comply with 91.127.

(c) Communications with other control towers. No person may, within an airport traffic area operate an aircraft to, from, or on an airport having a control tower that is operated by any person other than the United States unless—

(1) If that aircraft's radio equipment so allows, two-way radio communications are maintained between the aircraft and the tower; or

(2) If that aircraft's radio equipment allows only reception from the tower, the pilot has the tower's frequency monitored.

(d) Minimum altitudes. When operating to an airport with an operating control tower, each pilot of—

(1) A turbine-powered airplane or a large airplane shall, unless otherwise required by the applicable distance from cloud criteria, enter the airport traffic area at an altitude of at least 1,500 feet above the surface of the airport and maintain at least 1,500 feet within the airport traffic area, including the traffic pattern, until further descent is required for a safe landing:

(2) A turbine-powered airplane or a large airplane approaching to land on a runway being served by an ILS, shall, if the airplane is ILS equipped, fly that airplane at an altitude at or above the glide slope between the outer marker (or the point of interception with the glide slope, if compliance with applicable distance from clouds criteria requires interception closer in) and the middle marker; and

(3) An airplane approaching to land on a runway served by a visual approach slope indicator, shall maintain an altitude at or above the glide slope until a lower altitude is necessary for a safe landing.

However, subparagraphs (2) and (3) of this paragraph do not prohibit normal bracketing maneuvers above or below the glide slope that are conducted for the purpose of remaining on the glide slope.

(e) Approaches. When approaching to land at an airport with an operating control tower, each pilot of—

(1) An airplane, shall circle the airport to the left; and

(2) A helicopter, shall avoid the flow of fixed-wing aircraft.

(f) Departures. No person may operate an aircraft taking off from an airport with an operating control tower except in compliance with the following:

(1) Each pilot shall comply with any departure procedures established for that airport by the FAA.

(2) Unless otherwise required by the departure procedures or applicable distance from clouds criteria, each pilot of a large or turbine-powered airplane shall climb to an altitude of 1,500 feet above the surface as rapidly as practicable.

(g) Noise abatement runway system. When landing or taking off from an airport with an operating control tower, and for which a formal runway use program has been established by the FAA, each pilot of a turbine-powered airplane and each pilot of a large airplane, assigned a noise abatement runway by ATC, shall use that runway. However, each pilot has final authority and responsibility for the safe operation of his airplane and if he determines in the interest of safety that another runway should be used, ATC will assign that runway (air traffic and other conditions permitting).

(h) Clearances required. No pilot may, at an airport with an operating control tower, taxi an aircraft on a runway, or take off or land an aircraft, unless he has received an appropriate clearance from ATC. A clearance to "taxi to" the runway is a clearance to cross all intersecting runways but is not a clearance to "taxi on" the assigned runway.

91.89 Operation at airports without control towers.

Each person operating an aircraft to or from an airport without an operating control tower shall—

(a) In the case of an airplane approaching to land, make all turns of that airplane to the left unless the airport displays approved light signals or visual markings indicating that turns should be made to the right, in which case the pilot shall make all turns to the right;

(b) In the case of a helicopter approaching to land, avoid the flow of fixed-wing aircraft; and

(c) In the case of an aircraft departing the airport, comply with any FAA traffic pattern for that airport.

10579

CHAPTER 15

PRINCIPLES OF RADAR

The purpose of this chapter is to review the principles which determine the characteristics of radar circuits and to follow this review with a discussion of how these circuits are applied in a typical multipurpose pulse modulated radar set.

RADAR PERFORMANCE FACTORS

Among the principles which should be reviewed before continuing with the present discussion are certain factors which affect radar performance. Such factors are carrier frequency, pulse width and pulse repetition frequency, the power relation (relation between peak and average power), beam width, and scan rate. The choices of these arbitrary constants for a particular system are determined by its tactical use, the accuracy required, the range to be covered, the practical physical size, and the problem of generating and receiving the signal. Basic information concerning these factors may be found in chapter 15 of Basic Electronics, NavPers 10087-B.

PULSE SHAPE

The shape of the pulse determines range accuracy, minimum and maximum range, and resolution or definition of target. The pulse shape is of little importance in the detection of a target as long as it has sufficient power to cause a detectable echo at the receiver. However, the shape of the pulse is very important for range and Doppler velocity measurements. Pulsed Doppler radar depends on the duration of the waveform (pulse width) where it is used in moving target indicators (MTI).

For good range resolution (that is, the ability to separate two targets at nearly the same range), a narrow pulse width is required. If a pulse width of 6 microseconds is used, targets one-half mile apart may be resolved. Remember that 6.18 microseconds equals one-half radar mile.) When the two targets are separated by less than one-half mile, the leading edge of the pulse will be striking the farthest target while the trailing edge of the pulse is arriving at the closest target. This will cause both targets to appear as one on the scope. Thus the narrower the pulse, the better is the range resolution.

From the foregoing it would seem that an extremely narrow pulse would be desirable. This is not always the case. In order to be detected, a target must return an echo that is strong enough to cause an indication on the scope. The energy in the returned echo may be increased by increasing the peak transmitted power or by illuminating the target for a longer period of time. Longer target illumination may be achieved by increasing the pulse width. The peak power that a radar transmitter may produce is limited by the size and quality of its power supply, magnetron, waveguides, and other components. Therefore, it is usually more practical to design a radar with a lower peak power, increasing the pulse width to maintain a sufficient total energy level.

There are also other practical limitations to the minimum pulse width that can be used. Narrow pulses require a receiver with a greater bandwidth. (This is due to the harmonic content of a narrow pulse.) This reduces the gain of the receiver and increases noise.

The ideal pulse with perfectly vertical leading and trailing edges is not attainable. To have perfectly vertical sides (zero rise and fall times) would require an infinite bandwidth. In actual practice, rise and fall times of 0.001 microsecond (10 manoseconds) are commonplace. The steepness of the leading edge is a predominant factor in the accuracy of range

1055 1056

91.91 Avoidance of disaster areas.

(a) Designated disaster areas consist of that airspace below 2,000 feet above the surface within five statute miles of an aircraft or train accident, forest fire, earthquake, flood, or other disaster of substantial magnitude. (See fig. 9-7.) The designation of a disaster area is made in a Notice to Airmen.

(b) No person may operate an aircraft within a designated disaster area unless—

(1) That aircraft is participating in airborne relief activities under the direction of the Agency responsible for relief activities;

(2) That aircraft is being operated to or from an airport within the area, if that operation does not hamper or endanger relief activities;

(3) Flight around or above the area is impractical due to weather, terrain, or other considerations, if that en route operation through the area does not hamper or endanger relief activities and prior notice is given to the Air Traffic Service facility specified in the Notice to Airmen;

(4) It is specifically authorized under an IFR ATC clearance; or

(5) That aircraft is carrying properly accredited news representatives or persons on official business concerning the disaster, is operated in accordance with 91.79 and, unless otherwise authorized by the Agency responsible for relief activities, it is operated above altitudes used by relief aircraft and the operator has filed with the Air Traffic Service facility specified in the Notice to Airmen a flight plan that includes the following information:

(i) Aircraft identification, type, and color.

(ii) Radio communications frequencies to be used.

(iii) Proposed times of entry and exit of the disaster area.

(iv) Name of news media or purpose of flight.

(v) Any other information deemed necessary by ATC.

AC.127

Figure 9-7.—Avoidance of disaster area.

91.93 Flight test areas.

(a) No person may flight test an aircraft except over open water or sparsely populated areas having light air traffic.

91.95 Restricted and prohibited areas.

(a) No person may operate an aircraft within a restricted area (designated in Part 73) contrary to the restrictions imposed, or within a prohibited area, unless he has the permission of the using or controlling agency, as appropriate.

(b) Each person conducting, within a restricted area, an aircraft operation (approved by the using agency) that creates the same hazards as the operations for which the restricted area was designated, may deviate from the rules of this subpart that are not compatible with his operation of the aircraft.

91.97 Positive control areas.

(a) Except as provided in paragraph (b) of this section, no person may operate an aircraft within a positive control area designated in Part 71 unless that aircraft is—

(1) Operated under IFR at a specific altitude assigned by ATC;

(2) Equipped with instruments and equipment required for IFR operations and is flown by a pilot rated for instrument flight; and

(3) Equipped with—

(i) A coded radar beacon transponder, having a Mode A (military Mode 3) 64 code capability, replying to Mode 3/A interrogation with the code specified by ATC; and

(ii) A radio providing direct pilot/controller communication on the frequency specified by ATC for the area concerned.

(b) ATC may authorize deviations from the requirements of paragraph (a) of this section for operation in a positive control area. In the case of an inoperative transponder, ATC may immediately approve an operation allowing flight to continue to the ultimate destination, including any intermediate stops, or to proceed to a place where suitable repairs can be made, or both. A request for authorization to deviate from a requirement of this section must be submitted at least four days before the proposed operation, in writing, to the ATC center having jurisdiction over the positive control area concerned. ATC may authorize deviations on a continuing basis or for an individual flight, as appropriate.

91.99 Jet advisory areas.

(a) No person may operate an aircraft within a radar jet advisory area designated in Part 75 unless—

(1) That aircraft is operated under IFR at a specific altitude assigned by ATC; or

(2) If the aircraft is not so operated and—

(i) That aircraft is equipped with a functioning coded radar beacon transponder having a Mode A (military Mode 3) 64 code capability, that transponder is operated to reply to Mode 3/A interrogation with the code specified by ATC;

(ii) If that aircraft is not so equipped, it is operated under specific authorization from ATC; or

(iii) If radio failure prevents the receiving of that authorization, he maintains an appropriate VFR cruising flight level.

(b) No person may pilot an aircraft within a nonradar jet advisory area designated in Part 75 unless that aircraft is operated under—

(1) IFR at a specific altitude assigned by ATC; or

(2) Specific authorization from ATC.

91.101 Operations to, or over, Cuba.

No person may operate a civil aircraft from the United States to, or over, Cuba unless—

(a) Departure is from an international airport of entry designated in 6.13 of the Air Commerce Regulations of the Bureau of Customs (19 CFR 6.13); and

(b) In the case of departure from any of the 48 contiguous States or the District of Columbia, the pilot in command of the aircraft has filed—

(1) A DVFR or IFR flight plan as prescribed in 99.11 or 99.13 and

(2) A written statement, within one hour before departure, with the office of Immigration and Naturalization Service at the airport of departure, containing—

(i) All information in the flight plan;

(ii) The name of each occupant of the aircraft;

(iii) The number of occupants of the aircraft; and

(iv) A description of the cargo, if any.

This section does not apply to the operation of aircraft by a scheduled air carrier over routes authorized in operations specifications issued by the Administrator.

91.102 Flight limitation in the proximity of space flight recovery operations.

No person may operate any aircraft of United States registry, or pilot any aircraft under the authority of an airman certificate issued by the FAA within areas designated in a NOTAM for space flight recovery operations except when authorized by ATC, or operated under the control of the DOD Manager for Manned Space Flight Support Operations.

91.103 Operation of civil aircraft of Cuban registry.

No person may operate a civil aircraft of Cuban registry except in controlled airspace and in accordance with air traffic clearances or air traffic control instructions that may require use of specific airways or routes and landings at specific airports.

91.104 Flight limitations in proximity of the Presidential Party.

No person may operate an aircraft, over or in the vicinity of areas to be visited or traveled by the President, the Vice President, or other

10581

08201

public figures, contrary to the limitations specified in a Notice to Airmen (NOTAM).

Visual Flight Rules

91.105 Basic VFR weather minimums. (See fig. 9-8 and table 9-1.)

(a) Except as provided in 91.107, no person may operate an aircraft under VFR when the flight visibility is less, or at a distance from clouds that is less, than that prescribed for the corresponding altitude in table 9-1.

(b) When the visibility is less than 1 mile, a helicopter may be operated outside controlled airspace at 1,200 feet or less above the surface if operated at a speed that allows the pilot adequate opportunity to see any air traffic or other obstruction in time to avoid a collision.

(c) Except as provided in 91.107, no person may operate an aircraft, under VFR, within a control zone beneath the ceiling when the ceiling is less than 1,000 feet.

(d) Except as provided in 91.107, no person may takeoff or land an aircraft, or enter the traffic pattern of an airport under VFR within a control zone—

(1) Unless ground visibility at that airport is at least 3 statute miles; or

(2) If ground visibility is not reported at that airport, unless flight visibility during landing or takeoff, or while operating in the traffic pattern, is at least 3 statute miles.

(e) For the purpose of this section, an aircraft operating at the base altitude of a transition area or control area is considered to be within the airspace directly below that area.

AC.128
